Of this valuable machine, the invention of Mr. Lee of Cambridge, a side elevation is given in *fig. 963*, with the essential parts. The framing is supported by four upright posts, generally of oak, ash, or other hard wood. Two of these posts appear at *a*, and the connecting cross rails are at *c*. At *b* is a small additional piece of framing, which supports the hosiery's seat. The iron-work of the machine is bolted or screwed to the upper rails of the framework, and consists of two parts. The first rests upon a sole of polished iron, which appears at *n*, and to which a great part of the machinery is attached. The upper part, which is generally called the carriage, runs upon the iron sole at *n*, and is supported by four small wheels or trucks, as they are called by the workmen. At the upper part of the back standard of iron are joints, one of which appears at *q*; and to these is fitted a frame, one side of which is seen extending to *n*. By means of these joints the end at it may be depressed by the hosiery's hand, and it returns, when relieved, by the operation of a strong spring of tempered steel, acting between a cross bar in the frame, and another below. The action of this spring is very apparent in *fig. 966*. In the front of the frame, immediately opposite to where the hosiery sits, are placed the needles which form the loops. These needles, or rather hooks, are more or less numerous, according to the coarseness or fineness of the stocking; and this, although unavoidable, proves a very considerable abatement of the value of a stocking-frame. In almost every other machine (for example, those em-

played in spinning or weaving), it is easy to adapt any one either to work coarser or finer work, as it may be wanted. But in the manufacture of hosiery, a frame once finished, is limited for ever in its operation to the same quality of work, with this exception, that by changing the stuff, the work may be made a little more dense or flimsy; but no alteration in the size or quantity of loops can take place. Hence where the manufacture is extensively prosecuted, many frames may be thrown idle by every vicissitude of demand; and where a poor mechanic does purchase his own frame, he is for ever limited to the same kind of work. The gauge, as it is called, of a stocking-frame is regulated by the number of loops contained in three inches of breadth, and varies very much; the coarsest frames in common use being about what are termed four-tones, and the finest employed in great extent about twelve. The needles are of iron wire, the manufacture of which is very simple; but long practice in the art is found necessary before a needle-maker acquires the dexterity which will enable him both to execute his work well, and in sufficient quantity to render his labour productive.

The process of making the needles is as follows:—Good sound iron wire, of a proper fineness, is to be selected; that which is liable to split or splinter, either in filing, juncing, or bending, being totally unfit for the purpose. The wire is first to be cut into proper lengths, according to the fineness of the frame for which the needles are designed, coarse needles being considerably longer than fine ones. When a sufficient number (generally some thousands) have been cut, the wire must be softened as much as possible. This is done by laying them in rows in a flat iron box, about an inch deep, with a close cover; the box being filled with charcoal between the strata of wires. This box, being placed upon a moderate fire, is gradually heated until both the wires and charcoal have received a moderate red heat, because, were the heat increased to what smiths term the white heat, the wire would be rendered totally unfit for the subsequent processes which it has to undergo, both in finishing and working. When the box has been sufficiently heated, it may be taken from the fire, and placed among hot ashes until both ashes and box have gradually cooled; for the slower the wires cool, the softer and easier wrought they will be. When perfectly cool, the next process is to punch a longitudinal groove in the stem of every needle, which receives the point or barb, when depressed. This is done by means of a small engine worked by the power of a screw and lever. The construction of these engines is various; but a profile elevation of one of the most simple and commonly used will be found in fig. 966. It consists of two very strong pieces of malleable iron, represented at A and C, and these two pieces are connected by a strong well-fitted joint at N. The lower piece, or sole of the engine at C, is screwed down by bolts to a strong board or table, and the upper piece A will then rise or sink at pleasure, upon the joint N. In order that A may be very steady in rising and sinking, which is indispensable to its correct operation, a strong bridle of iron, which is shown in section at R, is added to C, and direct its motion. In the upper part of this bridle is a female screw, through which the forcing screw passes, which is turned by the handle or lever H. To the sole of the engine C is fixed a bolster of tempered steel, with a small groove to receive the wire which is to be punched; and in the upper or moving part A, is a sharp chisel, which descends exactly into the groove, when A is depressed by the screw. These are represented at V, and above N. At U is a strong spring, which forces up the chisel when the pressure of

the screw is removed. The appearance of the primer, when the finishing is finished, will be presented to the eye by inspecting fig. 974, p. 471. When the finishing is finished, the wire are to be brought to a smooth point by filing or honing, the point of which should be very smoothly done, as, besides pointing the wire, it is principally to remove the roughness which has been formed by the previous operation of twisting. The wire is next to be bent, in order to form the hook or barb, and this is done with a small piece of iron plate or dolly, which curves the point of the wire, and by its length regulates the length of the barb. The curve of the needle is now finished with a small hammer, to prevent it from turning in the socket in which it is afterwards to be put; and the point of the barb being a little curved by a pair of small pliers, the needle is completed.

In order to fit the needles to the frame, they are now cast into the sockets of lead, as they are called by the workmen, and this is done by placing the needles in an iron mould, which opens and shuts by means of a joint, and turning in the whole in a lathe or press. In some operations, two needles are cast into the same socket. The form of the needle, when complete and fitted to its place in the frame, will be seen in fig. 967, which is a profile view of the needle-bar passing through the needle.

967

of iron called a verge, to regulate the position of the needles. When placed over the bar resting against the verge, another plate of iron, generally lined with soft leather, is pressed down upon the sockets or leads, in order to keep them all fast. This plate and the screw appear at *t*. When the primer at *r* is forced down upon the barb, this sinks into the groove of the stem, and the needle is shut; when the primer rises, the barb opens again by its own elasticity.

The needles or hooks being all properly fitted, the next part of the stocking-frame to which attention ought to be paid, is the machinery for forming the loops; and this consists of two parts. The first of these, which sinks between every second or alternate needle, is represented at *a*, fig. 965, and is one of the most important parts of the whole machine. It consists of two moving parts; the first being a succession of horizontal levers moving upon a common centre, and called jacks, a term applied to vibrating levers in various kinds of machinery as well as the stocking-frame. One only of these jacks can be represented in the profile fig. 965; but the whole are distinctly shown in a horizontal position in fig. 968; and a profile upon a very enlarged scale is given in fig. 969. The jack shown in fig. 968, extends horizontally from *o* to *i*, and the centre of motion

968

969

is at *x*. On the front, or right hand of the Jack at *o*, is a joint suspending a very thin plate of polished iron, which is termed a sinker. One of these jacks and sinkers is allotted for every second or alternate needle. The form of the sinker will appear at *a*,

As the jacks are in order that all may be exactly uniform in shape, they are cast out and finished between two circular plates of iron, which serve as guides to correct the form of each. The lower end of the jack at *i*, is tapered to a point, and when the jacks are put in their several positions, they are secured by a small iron screw, one of which is represented at *t*, in fig. 96, each screw having a small conical end, each to receive the point of the jack, against which it presses by its own elasticity. In fig. 95, the centre is at *a*, the pointed tail is marked for want of room, the joint is at *o*, and the throat of the sinker, which forms the loop, is at *e*. The standards at *a*, upon which the jacks move, are called combs, and consist of pieces of flat round brass, pointed at the equal distance from each other. The cross bar *n*, which contains the whole, is of iron, with a perpendicular bar *e* or *o* on each side, leaving a vacancy between them, for a screw to pass the bottom part or ends of the combs. The combs are then placed in the bar, with a few pieces of brass called a *room*, between each, to ascertain and preserve their distances from each other. These combs are exactly of the same shape as the combs, but have no tails. When the jacks and the combs are placed in the bar, it is laid with clay or no to form a mould, into which is poured a sufficient quantity of melted tin. When the tin has had time to cool, the combs and the jacks having no tails are easily taken out, and the tin remains well fastened and secured by the tin, which has been fused entirely round them. Thus they form a complete set of standards for the jacks; and a hole being drilled through each jack and each comb, was put through all as a common screw for the whole.

The jacks and the combs being now used for every shorn or round needle, in order to complete this part of the operation, a second set of standards is prepared. These are in form and shape every way the same as the jack sinkers, but they are jointed at the top into pieces of tin, all of which are secured to the cross bar, *n*, fig. 95, and thus a chain of each kind descends between the needles, and the reason of two sets different in operation being employed, will be assigned in describing the mode of working the frame. The presser of the operation, of which something has already been said, appears at *r*; and of the two arms which support and give motion to it, one appears very plainly at *x*, its centre of motion being at *c*. The circular bend given to these arms, besides having an ornamental effect, is very useful, in order to prevent any part from interfering with the other parts which are brought, by elevating them entirely above them. The extremities of these arms at the termination of the bends behind, are connected by a cross bar, which has also a circular bend in the middle projecting downwards for a screw *s* similar to that already assigned. This bend is concealed in fig. 96, but visible in the front elevation, fig. 71. From the middle of the bend, the presser is connected with the middle treadle by a depending wire appearing at *u*, fig. 96, and thus, by the pressure of that treadle, the presser is forced down to close the barbs of the needle. The resistance of the presser is sometimes effected by means of a counterpoising weight passing over a pulley behind; and sometimes by the reaction of a wooden spring, formed of a strong hoop like that represented at *a*. The latter of these is preferred, especially by the Nottingham hosiers, because, as they assert, it makes the presser spring up with greater rapidity, and consequently saves time in working. How far this may be practically the case, it would be superfluous here to investigate; but it is obvious that the wooden spring, if very stiff, must add much to the hosier's exertion of his foot, already exercised against the united spring of all his barbs; and this inconvenience is

much improved of by those who have been accustomed to work with the common

At A are two rollers or wheels, of different diameters, revolving in opposite directions by which the jacks are relieved from the back springs, and then are drawn away to form the lower part of the machine. About the larger wheel is a band of unspun yarn, from which the extension of which are made in which is wound the yarn from the jacks from the back springs. The smaller roller by which the band is drawn over the ribbed roller, so that the thread is wound round the band, turns the jacks there is an inverted order. The movement of the loops at a point completely in the front elevation. The movement of the slur, as it is called, upon the jacks, will also be readily apparent by fig. 971. In the figure, eight jacks are represented in section, the tail part of three of which 1, 2, 3, are then wound up by the slur to its greatest length left or right; the fourth 4 is the act of taking, and the remaining four 5, 6, 7, and 8 are disengaged from the slur and have been released them. As the slur sets in the direction of the thread at a, the jacks are drawn the centre of the jacks, it is hardly necessary to remark, that the falling of the tails must of course depress the jacks by which the motion is done are made, the jacks sinkers falling successively from the loops on every subsequent

minor of following them, and suspending them from the bar as they appear in the diagram, the position of the bar being regulated by the line a, n, that when the slur is pulled down to the level of the former by the operator's hands, the whole frame will be completed, and the thread c, n, which is at 1 slack, will be brought to its full and proper degree of tension, which is regulated by stop screws, so as to be the proper amount at all times. The sinking of this second

set, in the way represented at fig. 973, where both kinds of sinkers appear in section, the right part representing what is done at the point at which the thread of the other operator runs the thread, and the dark part what is done. The second set, or as they are called, the lead sinkers, from the slur, in the way represented at fig. 973, where both kinds of sinkers appear in section, the right part representing what is done at the point at which the thread of the other operator runs the thread, and the dark part what is done. The second set, or as they are called, the lead sinkers, from the slur, in the way represented at fig. 974. The direction of the sinkers is expressed by the line a; the bar from which they are suspended will be at a; the top frame is in the direction from a to b; the back standards at n, and the joint at n, is the centre of motion. If it is pulled perpendicularly downwards, the spring c will be contracted, and its upper extreme point,

a, will be brought nearer to its lower extreme point v, which is fixed. Again, when the force which has depressed a is removed, the spring c will revert to its former state, and the sinkers will rise. The raising of the jack sinkers and jacks takes place at the same time, by the hooper raising his hands; and for the cause of this we must revert to fig. 975. The lead sinkers in raising lay hold of notches, which raise the extreme parts of the set of jacks x, z, which are called half-jacks. Between the extremities of these at x, z, is a cross bar, which, in descending, presses at the intermediate jacks behind the common centre, and restores them to their original posture where they are secured by the back springs, until they are again relieved by the operation of the slur recrossing at the next course.

Working of the frame.—In order to work a frame, the whole apparatus being previously put into complete order, the hooper places himself on the seat a, in front, and provides himself with a bobbin of yarn or mull. This bobbin he places loosely on a vertical pin of wire, driven into one side of the frame contiguous to the needles, so that it may turn freely as the stuff is unwound from it. Taking the thread in his hand, he draws it loosely along the needles, behind the barbs, and under the throats of the sinkers. He then presses down one of the treadles to pass the slur along, and unlock the jacks from the back springs, that they may fall in a common. When this is done, the number of loops thus formed is doubled by bringing down the lead sinkers, and the new formed loops are lodged under the barbs of the needles by bringing forward the sinkers. The preceding course, and former fabric, being then again pushed back, the barbs are shut by depressing the middle treadle, and forcing down the presser upon the needles. The former work is now easily brought over the slat needles, after which, by raising the hands, both sets of sinkers are raised; the jacks are locked by the back springs, and the hooper goes on to another course.

From this it will be apparent, that the work made in the outset is well founded, for there are in reality no equal or distant movements in the working-frame. Although the wheels are nearly the same, they revolve upon their respective axes, excepting that of the carriage which gives the horizontal motion to the stockers, and that to merely an alternate motion to foot wheel. Yet the frame is a machine which requires considerable experience and care, both to work it to advantage, and also to keep it in good order. The consequences arise greatly from the small principle in which a number of moving parts must be included. Owing to this, the needles, which constantly and delicately handle the threads, are easily bent or injured. The same circumstances apply to with equal or greater force to the stockers, which must be so very thin as to be easily injured. But as these must work freely, both in a perpendicular and horizontal direction, to work the machine in a very confined and limited space, the slightest variation in either, from being truly and equally placed, may daily injure the others. When a hosieler, either ignorant of the mechanical laws of their relation to each other, or not disposed to wait for the assistance of another, attempts to rectify a fault, he in most cases increases them tenfold, and renders the machine incapable of working at all, until repaired by some more experienced person. The consequence has given rise to a set of men employed in this trade, and designated by the name of upstitchers, and these people, besides setting new frames to work, have frequently more employment in repairing old ones injured by want of care or skill, than many country spinners, who live in unhealthy partiality, find in tampering with the disorders of their kind.

It is now necessary to go further into detail respecting a machine so well known, and which requires practical attention even more than most others. It may, therefore, be sufficient to describe shortly some of its varieties, the most common, and of which is the rib-stick frame.

Rib-stick frame.—This frame, which, next to the common frame, is most extensively in use, is employed for working those striped or ribbed stockings, which are very common in all the different materials of which hosiery is formed. In principle it does not differ from the common frame, and not greatly in construction. The preceding general description will nearly apply to this machine with equal propriety as to the former; that part, however, by which the ribs or stripes are formed, is entirely an addition, and to the application of this additional machinery it may be proper to pay the chief attention, referring chiefly to *fig. 971*, which is a front elevation. This figure has been already referred to for the illustration of those parts of the machinery which are common to both, and those parts therefore require no recapitulation. The principle of weaving ribbed hosiery has considerable affinity to that of weaving that kind of cloth which is distinguished by the name of twilling, for the formation of stripes, with some variation, arising merely from the difference of nature of the fabric. In cloth weaving, two different kinds of yarn intersect each other at right angles, are employed; in hosiery only one is used. In the weaving of cloth, striped as diversity, in the cotton hosiery trade and in the woollen manufacture, the stripes are produced by reversing these yarns. In hosiery, where only one kind of yarn is used, a similar effect is produced by reversing the loops. To effect this reversing of the loops, a second set of needles is placed upon a vertical frame, so that the heads of the barks may be nearly under those of the common needles. These needles are cast into an iron plate, pretty similar to the former, but more oblique or bevelled towards the point, so as to prevent obstructions in working them. They are also screwed in a bar of iron, generally lighter than the other, and secured by means of plates; this bar is not fixed, but has a pivot in each end, by means of which the bar may have a kind of oscillatory motion on these pivots. Two frames of iron support this bar; that in which it oscillates being nearly vertical, but inclined a little towards the other needles. *Fig. 975*, which is a profile elevation, will serve to illustrate the relative position of each bar to the other. The lower or horizontal frame, the ends only of which can be seen in *fig. 971*, under *o n*, appears in profile in *fig. 975*, where it is distinguished by *d*. The vertical frame at *w* is attached to this by two eccentric screws, which serve as joints for it to move in. On the top of this frame is the rib-needle bar at *f*, in *figs. 965* and *975*, and one needle is represented in *fig. 973* at *f*. At *g* is a small presser, to shut the barbs of the rib-needle, in the same manner as the large one does those of the frame. At *h* is one of the frame needles, to show the relative position of the one set to the other. The whole of the rib-bar is not fitted with needles like the other; for here needles are only placed where ribs or stripes are to be formed, the intervals being filled up with blank leads, that is to say, with sockets of the same shape as the others, but

without further, being merely designed to fill the bar and preserve the intervals. The raised flange depends from the middle bar, by which the necessary distance upon the upper surface is given. The rising and sinking motion is communicated to this flange by a chain which is at right to the other bars, and which are wrought by the hander's heel when necessary. The pressure takes place partly by the action of the screw pressure, and partly by the motion of the needles in descending. A small iron roller is placed behind the rib-frames, which raise as they descend, and serve to form the large part of the rib-frames.

In the working of raised hosiery, the plain and ribbed courses are wrought alternately. When the plain are formed, the rib-frames are raised between the others, but an additional shaft is supplied. The rib-frames intersecting the plain ones, namely lay half of the top thread, and by doing so, being it through that which was in the rib-frames before, give it an additional supply, which reverses the line of shading, and raises the rib above the plain intervals, which have only received a simple knitting.

HOT-FLUE is the name given in England to an apartment heated by means of steam pipes, in which padded and printed calicoes are dried hard. Fig 978 represents

sents the simplest form of such a flue, heated by the vertical round iron stove *B*, from whose top a wide square pipe proceeds upwards in a slightly inclined direction, which receives the current of air heated by the body and capital of the stove. In this wide

channel there are pulleys, with cords or bands which suspend by hooks and connect the web of cotton from the machine at *a*, where the operative sits, to near the point *A*, and back again. The strand may be repeated once or several times till the goods are properly dried. At *b* is the driving power connected with the main shaft *u* shown. Near the feet of the operative is the winding or reel upon which the woven goods are wound in an endless web, so that their removal in the hot-air channel can be continued without interruption, as long as may be necessary.

Fig. 977 is a cross-section of the apparatus of the regular hot-flue, as it is mounted in the most valuable shape of England, that of James Thompson, Esq., of Preston, near Chorley, Lancashire. It consists of an arched apartment, nearly 30 yards long, by 18 feet high, and 10 feet wide. Thompson about one-half of this gallery divides in a horizontal floor supported on arches, above which is the drying space, through which the goods are finally passed before they escape from the flue. After they have been previously exposed to the hot air, somewhat out of sight of the lower apartment. A large square flue covered with cast-iron plates runs along the whole bottom of the gallery. It is composed of two long parallel tubes, whose sections are seen at *u*, *v*, &c. fig. 977, covered with the cast-iron plates *r*, *r*, projected at their ends into one another. The thickness of these plates is increased progressively as they come nearer to the fire-places or furnaces. There are dampers which regulate the draught, and of course the heat of the stove. *A A* are the air-passages or vent holes, left in the side walls, and which by means of a long iron rod, mounted with iron plates, may be opened or closed to suit the exigencies. *A A* are the cast-iron supports of the tinned brass rollers which guide the goods along, and which are fixed to the cross pieces represented by *r*, *r*, fig. 977. *l l* are iron bars for supporting the ventilators or fans (see FURNACE and VENTILATION). These fans are here enclosed within a wire grating. They make about 3000 turns per minute, and expel the moist air with perfect effect. *s* indicates the position of the windows, which extend throughout the length of the building. *t* is a gas light jet, placed at the side of each window to supply illumination for night work. The pipe is stretched along the whole extent of the gallery, and runs through it in the space of one minute and a half, being expanded during its passage to the heat of 215° Fahr.

In fig. 978, *A* is the iron door of entrance to the hot-flue gallery; at *b* is the padding machine, where the goods are padded with the flannel material. The speed of this machine may be varied by means of the two conical drums *c*, *c*, which drive it; since, when the band *c c* is brought by its forks, and adjusting screws, nearer to the narrow end of the lower drum, the cylinder upon the same shaft with the latter is driven quicker; and *rev* *rev* Over *b* is the cords are shown for drawing the drum mechanism into gear with the main shaft band, *r*, *r*, *r*; or for throwing it out of gear. The pulleys *r r* carry the bands which transmit the motion to the padding machine. A cylindrical drum exterior to the hot-flue, covered with flannel, serves to receive the end of the series of pieces, and to draw them through the apartment. This mode of drying the padded cotton requires for each piece of 26 yards three pounds of coals for the furnace when a fan is employed, and four pounds without it. See CALICO PRINTING.

lessening the size of the pipes and hydraulic machinery, by affording a pressure of greatly increased intensity.

"The apparatus thus constructed for a water tower I named *"the Accumulator,"* from the circumstance of its accumulating the power carried by the engine in charging it. The accumulator is, in fact, a reservoir giving pressure by load instead of by elevation, and it is so constructed that of every portion of this load, is to equalize the strain upon the engine in cases where the quantity of power to be supplied is subject to great and sudden fluctuations.

"The construction of the accumulator is exhibited in fig. 979, and needs but

little explanation. A, cylinder, B, plunger; C, D, loaded weight case; E, F, guides for descent; G, pipe from forcing engine; H, pipe to hydraulic machine. It consists of a large cast-iron cylinder, fitted with a plunger, from which a loaded weight case is suspended, to give pressure to the water required by the engine. The load upon the plunger is so regulated as to produce a pressure in the cylinder equal to a given pressure in the machine, and the apparatus is made sufficiently capacious to contain the largest quantity of water which can be drawn from it at once by the machine, in accordance with the hydraulic machine with which it is connected. Whenever the engine pumps more water into the accumulator than passes direct to the hydraulic machine, the loaded plunger rises and makes room in the cylinder for the surplus; but when, on the other hand, the supply from the engine is less, for the moment, than the quantity required, the plunger, with its load descends and makes up the deficiency out of store.

"The accumulator also serves as a regulator to the engine; for when the loaded plunger rises to a certain height, it begins to close a throttle-valve in the supply pipe, so as gradually to reduce the speed of the engine until the descent of the plunger begins calls for an increased production of power.

"The introduction of the accumulator, which took place in the year 1851, gave a great impulse to the extension of water-pressure machinery, which is now either already applied, or in course of being applied, to the purpose of cransage throughout all the great dock establishments in London, as also to a considerable extent in Liverpool and other places. I have also applied it extensively to railway purposes, chiefly under the direction of Mr. Brunel, who has found a multitude of cases, involving lifting or tractive power, in which it may be made available. Most of these applications are well exemplified at the new station of the Great Western Railway Company in London, where the loading and unloading of trucks, the hoisting into warehouses, the lifting of loaded trucks from one level to another, the moving of turn-tables, and the hauling of trucks and traversing machines are all performed, or about to be so, by means of hydraulic pressure supplied by one central steam-engine with connected accumulators. Mr. Rendel also, after having successfully adopted the low-pressure system to the working of the gates and shuttles at Grimsby, has since applied the high-pressure, or accumulator system, to the same purposes at other new docks, and a similar adaptation is being made by other eminent engineers at most of the new docks now in course of construction.

"I have also adapted hydraulic machinery to the opening and closing of swing-bridges and draw-bridges of large dimensions, and, in fact, there is scarcely any mechanical operation to which human labour has been hitherto applied as a mere

raising power, which may not be efficiently performed by means of water-pressure containing great incompressibility and accumulation. Even if least injury be treated as the basis of the power, the accumulation of an accumulation will be many times both extensive volume and various deposits. For example, a pair of heavy lock-gates requires the raising a resistance of a magnitude the raising of many times before a gate could be raised successfully, viz. when the gates are being opened or raised. Now, if an accumulator, charged by hand-pumps, were used, the latter cylinders would be constantly under the requirement, and the power required in the accumulation by the continuous pressure of pumping would be given out in a continuous form, and thus the ultimate result would be efficient with fewer loads and greater regularity than where constant pressure is thereby required.

The form of pump-motors which I generally use for charging the accumulator is represented in the sketch. It consists of a horizontal steam-cylinder, with two

force pumps connected directly with the piston. These force pumps are supplied with water from a cistern over the engine room, into which the water discharged by the cranes is generally brought back by a return-pipe, so that the water is not wasted, but remains continuously in use.

With a pressure representing a column of 1500 feet, the loss of head by friction in the pipes forms so small a deduction from the entire column as to be a matter of no consideration, and consequently the distances at which the engine may be situated from the points where the hydraulic machines may be placed is of little importance, except as regards the cost of the pipe. It is advisable, however, if the pipe be very long, to apply an accumulator at each extremity, so as to charge the pipe from both ends.

With regard to the mechanism of hydraulic cranes, the arrangement which I first adopted, and have ever since adhered to, consists of one or more hydraulic presses with a set of cylinders, used in the inverse order of load and pressure, for the purpose of obtaining an extended motion in the chain from a comparatively short stroke of the pistons. This construction, which characterizes nearly all the earlier forms of the hoisting and hauling machines to which I have applied hydraulic pressure is exhibited in fig. 281, which represents one of these presses with cylinders attached, to multiply the motion tenfold. In cases where the resistance to be overcome is very considerably, I generally employ two such cylinders, with rams or pistons acting either separately or conjointly upon the same set of multiplying sheaves, according to the amount of power required.

In hydraulic cranes the power is applied, not only for lifting the load, but also for swinging the job, which latter object is effected by means of a rack or chain operating on the base of the movable part of the crane, and connected either with a cylinder and piston having a ternate motion, like that of a steam engine, or with two presses applied to produce the same effect by alternate action.

The absence of any sensible elasticity in water renders the motions resulting from its pressure capable of the most perfect control, by means of the valve which regulates the inlet and outlet passages of the machines; but this very property, which gives so much certainty of action, tends to cause shocks and strains to the machinery, by resisting the momentum acquired by the moving parts. Take, for example, the case

of an hydraulic crane, weighing several tons, is suspended on the job, the machine being produced by the water working on one side of a piston and escaping from the

351

other. Under such circumstances, if the water-pump be suddenly stopped by the revolving valve, the piston and the piston-rod, impelled forward by the momentum of the loaded job, the rest by an unyielding body of water deprived of outlet, would be brought to rest abruptly, as to cause, in all probability, the breakage of the machine. So also, in lowering a heavy weight with considerable velocity, if the escape-pipe be too suddenly closed, a similar risk of injury would arise from the abrupt stoppage of the weight, if a remedy were not provided; but these liabilities are effectually removed by applying, in connection with the water-passage to the cylinder, a small check-valve, opening upwards against the pressure into the supply-pipe, so as to prevent the piston-water in the cylinder to be pressed back into the pipe whenever it becomes exposed to a compressive force exceeding the pressure on the accumulator. By this means all jerks and concussion are avoided, and a perfect control over the movement of the machine is combined with great uniformity of action.

With regard to the kind of valves used for water-pressure machinery, I find that either lift-valves or slide-valves may be effectually applied, and kept tight under heavy pressures, provided that they be excluded from the water, and the valves be made of proper material.

In cases where a more perfect control is required than multiplying check-valves will sufficiently afford, I employ another method of various constructions. For heavy pressures, such as an accumulator affords, an arrangement consisting of three plungers, connected with a triple-check, and bearing a general resemblance to a three-throw plunger pump, is well adapted for the purpose. The admission and exhaust valves are acted upon by rods, pressed down by weights and levers, and fitted in proper rotation by pins fixed for that purpose upon a separate shaft, and these valves are associated with relief-checks, to obviate the concussion which would otherwise be liable to take place at the turn of each stroke.

The liability of water-pressure machinery to be deranged by frost has often been adduced as an objection to its use; and upon this point I may observe — first, that I have never experienced any interference from this cause when the machines were placed, as they generally are, beneath the surface of the ground, or within a building; and secondly, that when they are unavoidably exposed, all risk may be prevented by letting out the water in frosty weather whenever the machines cease working.

When the working power consists of a natural column of water, the pressure rarely exceeds 250 grs per foot, and in such cases I have employed the rotative action of a pair of cylinders and plungers, with slide-valves, resembling in some degree those of a high-pressure engine, but having relief-valves, to prevent check at the turn of the stroke. *Fig. 98* shows a slide-valve adapted for the turning apparatus of a crane, but the relief-checks of which are equally applicable to a water-pressure engine of the common construction. Two of these check open against the pressure in the supply-pipe, so as to afford an escape for the water, which would otherwise be shut up in the cylinder when the exhaust-port closes, and the other two communicate with the discharge-pipe, so as to draw in a portion of water to fill up the small vacancy which would otherwise be left in the cylinder on the closing of the admission-port, a, supply pipe; b, exhaust pipe; c, d, pipes to cylinder; e, f, checks opening against

power, &c., which spring from exhaust. About four years ago I recommended the application of this principle to Mr. Harrison's last patent in Northampton, at the request of Mr. Sayer. Mr. Harrison's well-known patent, and two more, have recently been added at the same place. They are used for creating vapour, for heating materials from the bottom, for pumping water, and for driving a steam saw and other machinery. The Water-rate can be increased, as follows.

"If in progress of time railways should be generally extended into mountainous districts, as is to be done from Newcastle for manufacturing purposes, the rapid stream which should be such, to drive and pump the steam engines, and to give power and water, and may thus be adapted for the application of water power, &c., in various forms."

"The object, however, which I have chiefly had in view, is to give a new method of the subject, the time to provide, in a mountainous district, a method of working a machinery of machinery, a method in the action, and extending over a large area, by means of transmission of power, produced by a steam engine and steam engine of a central point. The reason made of machinery power by shafting would only be applied in cases where the machinery were not used with a small engine, and where the transmission of power necessary to meet varying requirements, and extend that which a few wheels would affect, compressed or exhausted air was almost equally applicable to the purpose I contemplated, in consequence of the many objections which are thereby avoided, as well as the liability to leakage, which, in an extended system of pipes and machinery, requiring a multitude of joints, valves, and fittings, surfaces, would form an insurmountable difficulty. But the use of water as a medium of transmission is free from all these objections, and its fitness for the purpose intended is now thoroughly established by the results which have been obtained."

HYDRAULIC MACHINERY for MINES. See WATER AND WATER PRESSURE FOR MINES, TERMINES.

HYDRAULIC PRESS. See WATER PRESSURE MACHINERY.

HYDRIODIC ACID (*Acide Hydrique*, Fr.; *Hydrojodine*, Germ.) is an acid formed by the combination of 127 parts of iodine with 1 part of hydrogen by weight, and by measure equal volumes of iodine vapour and hydrogen combined without condensation. It is obtained pure and in the gaseous state by introducing into a glass tube, closed at one end, a little iodine, then a small quantity of roughly-powdered glass moistened with water, upon this a few small fragments of phosphorus, and lastly more glass; this order, iodine, glass, phosphorus, glass, is repeated until the tube is two-thirds filled. A cork and narrow bent tube are then fitted and gentle heat applied, when the hydriodic acid is liberated, and may be collected in dry bottles by the displacement of air. Another process is to place in a small retort 10 parts of iodide of potassium with 5 of water, add 20 parts of iodine, then drop in gradually 1 part of phosphorus and into small pieces, and apply a gentle heat; hydriodic acid will be formed abundantly, and may be collected as before stated. The following equation expresses the reaction—

Hydriodic acid greatly resembles hydrochloric acid; it is colourless, and highly acrid, it fumes in the air, and is very soluble in water. Its density is 4.4, and under strong pressure condenses to a yellowish liquid, which solidifies at 100° Fahr.

Hydriodic acid in solution is much more easily prepared, by suspending iodine in water, and passing a stream of washed hydrosulphuric acid through it until the colour disappears; it is then heated to expel the hydrosulphuric acid, then allowed to rest, when it may be decanted from the precipitate of sulphur. The reaction consists simply in the displacement of the sulphur by the iodine, $HS + I = HI + S$.

This liquid may be evaporated until it acquires a density of 1.7, when it consists of $HI + 111H_2O$. It then distils at 247° Fahr. without decomposition. The solution cannot be long kept, it being decomposed by the oxygen of the air with the liberation of iodine, which imparts a dark colour to it. Chlorine decomposes it instantly, with liberation of the iodine.

The solution of hydriodic acid and of the iodides possess the power of dissolving a considerable quantity of iodine, forming a dark solution. — H. K. H.

HYDROBROMIC ACID. *HBr.* See BROMINE.

HYDRO-CARBON. See CARBURETTED HYDROGEN.

HYDROCHLORIC ACID. (*Chlorhydrique*, Fr.; *Salzsäure*, Germ.) A compound of chlorine and hydrogen which is a colourless gas of a peculiar suffocating, pungent odour; it reddens vegetable blues, but possesses no bleaching property. The solution of hydrochloric acid in water is the MURIATIC ACID and SPIRIT OF SALT of commerce; absently *Marine Acid*. 2 volumes of chlorine and 2 volumes of hydrogen combine to form 4 volumes of this acid. HCl ; eq. 36.5. It is best prepared by heating a mixture of 6 parts of chloride of sodium (*common salt*) and 10 parts of concentrated sulphuric acid previously diluted with 4 parts of water, in a capacious glass retort, connected with a set of Woulfe's bottles. This acid is extracted on a large scale from sea-salt, by the action of sulphuric acid and a moderate heat; but it was originally obtained from the salt by exposing a mixture of it and of common clay to ignition in an earthen retort. The acid gas which exhales is rapidly condensed by water. 100 cubic inches of water are capable of absorbing no less than 48,000 cubic inches of the acid gas, whereby the liquid acquires a specific gravity of 1.2105 and a volume of 143 cubic inches. This vast condensation is accompanied with a great production of heat; whence it becomes necessary to apply artificial refrigeration, especially if a strong *acid* as the above is to be prepared. In general, the muriatic acid of commerce has a specific gravity varying from 1.15 to 1.20, and contains, for the most part, considerably less than 40 parts by weight of acid gas in the hundred. The above stronger acid contains 42.66 per cent. by weight; for when a cubic inch of water, which weighs 252.5 grains, has absorbed 4.0 cubic inches—160 grains of gas; and $332.5 + 160 = 492.5$; then $440.5 : 160 :: 100 : 42.66$. In general a very good approximation may be found to the percentage of real muriatic acid, in any liquid sample, by multiplying the decimal figures of the specific gravity by 200. Thus, for example, at 1.160 we shall have by this rule $0.162 \times 200 = 32.4$, for the quantity of gas in 100 parts of the liquid. Muriatic acid gas consists of chlorine and hydrogen combined, without condensation, in equal volumes. Its specific gravity is 1.247, air = 1.000.

By sealing up muriate of ammonia and sulphuric acid, apart, in a strong glass tube re-curved, and then causing them to act on each other, Sir H. Davy procured liquid muriatic acid. He justly observes, that the generation of elastic substances in close vessels, either with or without heat, offers much more powerful means of approximating their molecules than those dependent on the application of cold, whether natural or artificial; for as gases diminished only $\frac{1}{10}$ in volume for every degree of Fahrenheit's scale, beginning at ordinary temperatures, a very slight condensation only can be produced by the most powerful freezing mixtures, not half so much as would result from the application of a strong flame to one part of a glass tube, the other part being of ordinary temperature; and when attempts are made to condense gases into liquids by sudden mechanical compression, the heat instantly generated presents a formidable obstacle to the success of the experiment; whereas, in the compression resulting from their slow generation in close vessels, if the process be conducted with common precautions, there is no source of difficulty or danger; and it may be easily assisted by artificial cold, in cases where gases approach near to that point of compression and temperature at which they become vapours.—*Phil. Trans.* 1483.

The muriatic acid of commerce has usually a yellowish tinge, but when chemically pure it is colourless. It fumes strongly in the air, emitting a corrosive vapour of a peculiar smell. The characteristic test of muriatic acid in the most dilute state, is nitrate of silver, which causes a curdy precipitate of chloride of silver.

The preparation of this acid upon the great scale is frequently effected in this country by acting upon sea-salt in hemispherical iron pots, or in cast-iron cylinders, with concentrated sulphuric acid; taking 6 parts of the salt to 5 of the acid. The mouth of the pot may be covered with a slab of siliceous freestone, perforated with two holes of about two inches in diameter each, into the one of which the acid is poured by a funnel in successive portions, and into the other, a bent glass, or stone-ware tube, is fixed, for conducting the disengaged muriatic gas into a series of large globes of bottle glass, one-third filled with water, and laid on a sloping sand-bed. A week is commonly employed for working off each pot; no heat being applied to it till the second day.

The decomposition of sea-salt by sulphuric acid was at one time carried on by some French manufacturers in large leaden pans, 10 feet long, 5 feet broad, and a foot deep, covered with sheets of lead, and luted. The disengaged acid gas was made to circulate in a conduit of glazed bricks, nearly 650 yards long, where it was condensed by a sheet of water exceedingly thin, which flowed slowly in the opposite direction of the gas down a slope of 1 in 200. At the end of this canal nearest the apparatus, the muriatic acid was as strong as possible, and pretty pure; but towards the other end, the water was hardly acidulous. The condensing part of this apparatus was therefore

tolerable quantity, but as the decomposition of the salt could not be confined to the lower part, the acid mixture had to be drawn out of flame, in order to be completely decomposed in a reverberatory furnace; in this way nearly 50 per cent. of the muriatic acid was lost. And besides, the great quantity of gas given off during the emptying of the lead chambers was apt to suffocate the workmen, or seriously injured their lungs, causing severe bronchitis. The ready exit of muriatic acid is so considerable, and the loss of it incurred in the preceding process is of such consequence, that subsequently, both in France and in England, instead of soda, for the soda manufacture, has been procured with the decompositions of the muriatic acid in the air. In the method now lately resorted to, the gaseous products are exhausted from extensive vats, where currents of water come from them and carry them off into the river. The surrounding vegetation is thereby saved in some measure from being burned up, an accident which was previously liable to happen when first produced the floating gases upon the ground. At Newcastle, Liverpool, and Manchester, where the consumption of muriatic acid is so great, and in consequence of the manufacture of soda, this process is now practised upon a vast scale.

The apparatus for condensing muriatic acid gas has been modified and changed, of late years, in many different ways.

The Hastringes apparatus. At the end of a reverberatory furnace, opening into a lead trough or pan, about 1 foot deep, of a width equal to that of the interior of the furnace, that is, about 5 feet wide, and 6½ feet long, is enclosed in masonry, having its upper edges covered with cast-iron plates or fire tiles, and placed upon a level with the passage of the smoke as it escapes from the reverberatory. The arch which covers that pan forms a continuation of the roof of the reverberatory, and is of the same height. The flame which proceeds from the furnace contains the murex of salt and sulphuric acid is made to escape between the vault and the surface of the iron plates or fire tiles, through a passage only 4 inches in height. When the heated air and vapours reach the extremity of the pan, they are reflected downwards, and made to return beneath the bottom of the pan, in a row, which is afterwards directed so as to lead the smoke into two lateral flues, which terminate in the chimney. The pan is thus surrounded as it were with the heat and flame discharged from the reverberatory furnace. A door is opened near the end of the pan, for introducing the charges of sea-salt, amounting to 12 bags of 2 cwt. each, or 24 cwt. This door is then luted on as tightly as possible, and for every 100 parts of salt, 110 of sulphuric acid are poured in, of specific gravity 1.391, containing 57 per cent. of dry acid. This acid is introduced through a funnel inserted in the roof of the furnace. Decomposition ensues, muriatic acid gas mingled with steam is disengaged, and is conducted through 4 stone-ware tubes into the refrigerator, where it is finally condensed. These refrigerators consist of large stone-ware carboys, called *dame-jars* in France, to the number of 7 or 8 for each jupe, and arranged so that the neck of the one communicates with the body of the other; thus the gas must traverse the whole series, and gets in a good measure condensed by the water in them, before reaching the last.

When the operation is finished, the door opposite the pan is opened, and the residuum in it is discharged, in the form of a fluid magma, upon a square bed of bricks, exterior to the furnace. This paste speedily concretes on cooling, and is then broken into fragments and carried to the soda manufactory. The immense quantity of gas exhaled in discharging the pan, renders this part of the operation very painful

283

to the workmen, and wasteful in reference to the production of muriatic acid. The difficulty of luting securely the cast-iron plates or fire tiles which cover the pan, the

impossibility of completing the decomposition of the salt, since the residuum must be run off in a liquid state, finally, the damage sustained by the melting and corrosion of the lead, &c., are among the causes why no more than 80 or 90 parts of muriatic acid at 1.179 are collected, equivalent to 25 per cent. of real acid for every 100 of salt employed, instead of much more than double that quantity, which it may be made to yield by a well conducted chemical process.

The cylinder apparatus is now much esteemed by many manufacturers. *Fig. 883* represents, in transverse section, a bench of iron cylinder retorts, as built up in a proper

furnace for producing muriatic acid; and *fig. 884* a longitudinal section of one retort with one of its carboys of condensation. *a* is the grate; *b*, a fireplace, in which two iron cylinders *c c*, are set alongside of each other. They are $5\frac{1}{2}$ feet long, 20 inches in diameter, about $\frac{1}{4}$ of an inch thick, and take 16 cwt. of salt for a charge; *d* is the ash-pit; *e e* are cast-iron lids for closing both ends of the cylinders; *f* is a tube in the posterior lid, for pouring in the sulphuric acid; *g* is another tube, in the anterior lid, for the insertion of the bent pipe of hard glazed stoneware *h*;

i is a three-necked stoneware carboy; *k* is a tube of safety; *l*, a tube of communication with the second carboy; *m m m* are the flues leading to the chimney *n*.

After the salt has been introduced, and the fire kindled, 82½ per cent. of its weight of sulphuric acid, of sp. gr. 1.80, should be slowly poured into the cylinder through a lead funnel, with a siphon-formed pipe. The three-necked carboys may be either placed in a series for each retort, like a range of Woulfe's bottles, or all the carboys of the front range may be placed in communication with one another, while the last carboy at one end is joined to the first of the second range; and thus in succession. They must be half filled with cold water; and when convenient, those of the front row at least, should be plunged in an oblong trough of running water. The acid which condenses in the carboys of that row is apt to be somewhat contaminated with sulphuric acid, muriate of iron, or even sulphate of soda; but that in the second and third will be found to be pure. In this way 100 parts of sea-salt will yield 180 parts of muriatic acid, of sp. gr. 1.19; while the sulphate of soda in the retort will afford from 208 to 210 of that salt in crystals.

It is proper to heat all the parts of the cylinders equally, to insure the simultaneous decomposition of the salt, and to protect it from the acid; for the hotter the iron, and the stronger the acid, the less erosion ensues.

Some manufacturers, with the view of saving fuel by the construction of their furnaces, oppose to the flame as many obstacles as they can, and make it perform numerous circulations round the cylinders; but this system is bad, and does not even effect the desired economy, because the passages, being narrow, impair the draft, and become speedily choked up with the soot, which would be burned profitably in a freer space; the decomposition also, being unequally performed, is less perfect, and the cylinders are more injured. It is better to make the flame envelope at once the body of the cylinder; after which it may circulate beneath the vault, in order to give out a portion of its caloric before it escapes at the chimney.

The fire should be briskly kindled, but lowered as soon as the distillation commences; and then continued moderate till the evolution of gas diminishes, when it must be heated somewhat strongly to finish the decomposition. The iron door is now removed, to extract the sulphate of soda, and to recommence another operation. This sulphate ought to be white and uniform, exhibiting in its fracture no undecomposed sea-salt.

Liquid muriatic acid has a very sour corrosive taste, a pungent suffocating smell, and acts very powerfully upon a vast number of mineral, vegetable, and animal substances. It is much employed for making many metallic solutions; and in combination with nitric acid, it forms the aqua regia of the alchemists, so called from its property of dissolving gold. See SODA MANUFACTURE.

Table of Hydrocyanic Acid by Dr. Ure

Atmospheric Pressure	Specific Gravity	Volume of Gas	Weight of Gas	Atmospheric Pressure	Specific Gravity	Volume of Gas	Weight of Gas

HYDROCYANIC ACID. Syn. *Cyanhydric acid*, *Prussic acid*, CNH . This highly important acid is regarded by all chemists as being formed on the exact type of the ordinary inorganic hydracids, such as the hydrochloric or hydriodic. The compound radical analogous to chlorine, which is contained in it, has received the name of cyanogen, and possesses the formula CN . That this body is precisely analogous in its relations to the simple salt radicals is rendered certain by numerous facts. It combines directly with metals to form compounds: it possesses the same vapour volume, and unites with hydrogen to form a hydracid, which in its turn decomposes the metallic oxides with formation of water. Thus we have, with metallic oxides and hydrochloric acid (M standing for a metal), $\text{MO} + \text{HCl} = \text{MCl} + \text{HO}$, and with hydrocyanic and metallic oxides (Cy standing for cyanogen), $\text{MO} + \text{HCy} = \text{MCy} + \text{HO}$. Two volumes of chlorine and two of hydrogen yield four volumes of hydrochloric acid gas, and two volumes of cyanogen with two of hydrogen yield four volumes of hydrocyanic acid. The density of the vapour of hydrocyanic acid is consequently 0.9476. The theoretical number being 0.9343. Its density in the fluid state is 0.6967 at a temperature of 64° . It boils at 80°F . at ordinary pressures.

Hydrocyanic acid is never prepared in the anhydrous state except as a curiosity or for the purpose of scientific investigation. In fact it cannot be long preserved of great strength; a somewhat complex decomposition invariably taking place in it, with production of brown adhesive matters containing cyanide of ammonia, and also a substance by some considered to be an acid, and known as the azim . Paracyanogen is probably formed at the same time. The constitution of azuric acid is by no means well known, and even its very existence, as a definite chemical substance, is doubtful. It is singular that the presence of a mineral acid greatly retards the decomposition of prussic acid, especially if it be dilute: the pharmacopœian acid consequently may be preserved of uniform strength, in well filled and closely stoppered

bottles, for almost any length of time. The deadly nature of prussic acid unfortunately causes it to be only too frequently resorted to by the despairing or the murderer. Fortunately, however, in spite of its toxicity, the chemist possesses excellent means for its detection.

Preparation.—1. *Hydrated acid.* As prussic acid is largely employed in medicine, but in a very dilute form, it is usual to prepare it and dilute until of the proper degree of strength. The following process for preparing it will be found to give a satisfactory result, and, moreover, it may be performed on any quantity of materials. The apparatus for the purpose will vary with the scale to which the experiment is to be made. If on a few ounces, glass retorts and flasks answer well, if good condensation is ensured, by means of a Liebig's condenser well supplied with very cold water. If a large quantity of prussic acid is to be made, such as several gallons, the apparatus should consist of a retort or still with broad jacket by gridding. The head should be capable of adjustment with a steam-water adapter to a worm of the usual material enclosed in a tub of water. The joints are to be luted with a mixture of one handful of almond meal and five handfuls of linseed meal, worked with water to the consistency of putty. A solution of rough chloride of calcium in water is to be made and placed in a large iron pan, with a cover so contrived as to permit the still to drop in up to the flange. 14 parts of yellow prussiate of potash are then to be bruised in a mortar and mixed with dilute sulphuric acid prepared by adding 6 parts of sulphuric acid (density 1.850) to 43 of water. The head being luted on, a fire is to be kindled in the furnace under the iron pan, and the chloride of calcium bath is to be kept boiling constantly until 6 parts of acid have distilled over. The neck of the still should be placed in the funnel which conducts the acid to the Winchester quart bottles which are to contain the product, and a piece of wet bladder is to be stretched over the funnel to prevent evaporation of the acid into the laboratory. The worm used for the purpose must be ascertained to be perfectly clean, and, if prussic acid is to be frequently made, should be kept specially for that operation. To each Winchester quart of the acid distilling over, one drop of sulphuric acid may be added to insure its keeping. But the acid thus prepared generally keeps for a long time even without this precaution, owing probably to small traces of the sulphuric acid being carried over during the distillation.

It is quite impossible to conduct the operation so as to yield a product of uniform strength; it is absolutely necessary, therefore, to determine the percentage of real hydrocyanic acid, and dilute it to the required degree. It fortunately happens that 1 grain of hydrocyanic acid yields almost exactly 5 grains of cyanide of silver; for one equivalent of acid = 27 produces 1 equivalent of cyanide of silver = 134, so that $27 : 134 :: 1 : 4.96$. The acid produced will have, probably, to be reduced to one of two standards; namely, the so-called Scherck's strength, containing 3 per cent. of acid, or the P.L., containing 2 per cent.; 100 grains of the former should, consequently, yield 23 grains, and 100 of the P.L. 10 grains of cyanide of silver. In either case the calculation becomes obvious.

2. *The anhydrous acid.* Several processes for conducting this dangerous operation are known; the following is, perhaps, the most generally convenient. A large glass retort is so arranged that its neck is directed upwards at an angle of about 45° ; a cork fitted to the aperture in the neck connects a glass tube with a bottle containing a little chloride of calcium. From the latter vessel another tube proceeds to a U tube containing fragments of chloride of calcium, and from the latter a third, conducting the dehydrated vapour of prussic acid to an upright glass tube contained in a mixture of potash, 7 of oil of vitriol, and 14 of water. The retort is to be heated with a charcoal fire, and the temperature of the bottle and U tube, containing the chloride of calcium, is not to be allowed to fall below 90° , in order to prevent condensation of the anhydrous prussic acid taking place anywhere except in the tube contained in the freezing mixture. The vapour of anhydrous prussic acid is so dangerous that the greatest precaution must be taken to prevent inhaling the smallest portion.

Detection of prussic acid.—When prussic acid exists in moderate quantity in a solution it may be detected by first adding a few drops of potash, then a mixture of protosulphate and persulphate of iron, and finally a little hydrochloric acid; a bright blue precipitate indicates the presence of the acid. A much more delicate test, and one that is applicable when, from the dilution of the solution, the salts of iron are no longer capable of acting, is by the conversion of the prussic acid into sulphocyanide of ammonium. For this purpose the prussic acid is to be warmed on a watch glass with a drop of sulphide of ammonium, until the solution has become colourless. The addition of a trace of a solution of a persalt of iron will show, by the formation of a blood red colour, the presence of the acid sought. A very neat mode of applying this test is to place one drop of sulphide of ammonium on a watch glass inverted over

another containing the expanded fluid. On leaving the apparatus in a warm place, arranged in this manner, for a short time, the water vapor will be found to remain nearly motionless of expansion, which, after drying, will be in a state well adapted for showing the reaction with a peroxide of iron—C. G. W.

HYDRODYNAMICS. The terminal part of a science which treats of the motion of fluids. This science has, of course, most important bearings on the propulsion of steam, water-wheels, &c., employed to facilitate the operation of the mine. It is not however possible to embrace this, which belongs to mechanical engineering, in this work.

HYDRO-EXTRACTOR. A name sometimes given to the machine employed for expelling the water from waxes, gums, &c. See DISTILLATION.

HYDROFLUORIC ACID. It was discovered by J. W. Khardt, in 1780, that fluor spar and oil of vitriol would not run glass. Schlegel, in 1771, discovered that this peculiar property was due to the liberation of an acid from the fluor spar.

Hydrofluoric acid is thus obtained by placing finely powdered fluor spar in a leaden retort, and twice its weight of highly concentrated oil of vitriol. By a gentle heat the gas is distilled over, which must be collected in a receiver, in which, by means of a freezing mixture, it may be condensed into a liquid. If a solution of this acid in water is required, the extremity of the tube from the retort is carried into a vessel of water.

Hydrofluoric acid attacks glass with great readiness, by acting on its silica.

Glass upon which any design is to be etched, is covered with an etching wax, and the design made in the usual manner; this is placed over a leaden vessel, in which is a mixture of fluor spar and oil of vitriol; a gentle heat being applied, hydrofluoric acid escapes, and immediately attacks the glass. See ETCHING.

HYDROGEN. (Eng. and Fr. *Wasserstoff*, Germ.) A permanently gaseous, elementary body, the lightest of all known substances, its specific gravity being 0.069; 100 cubic inches weighing, under ordinary pressure and temperature, only 2.14 grains. It is therefore nearly 14.5 times lighter than atmospheric air.

From its extreme lightness it was formerly used for filling balloons, but has been superseded for that purpose by ordinary coal gas, which can be produced at a much cheaper rate; the difference of buoyant power being compensated by increasing considerably the size of the balloon. It is itself inflammable, but not a supporter of combustion, its combination with oxygen forming water, which contains $\frac{1}{8}$ th of its weight of hydrogen.

It is generally prepared by the action of dilute sulphuric acid on zinc, although there are many other processes which furnish it; as the decomposition of steam by iron filings with the aid of heat, &c.

In the act of combining with oxygen, as when burnt in the oxyhydrogen blow-pipe, the greatest possible heat is obtained; a piece of stout platinum wire being fused when placed in the flame, which cannot be effected by the greatest heat obtained in our furnaces.

Hydrogen is sometimes used for soldering metals; in which process it is requisite to bring the two surfaces of the metal together in a perfectly metallic state at a high temperature. Hydrogen effects this completely; by its combustion it supplies the heat, and by entering into combination with the oxygen of the air, prevents the formation of oxides, which are so easily formed at the temperature required for the melting of the metals, and which, when present, prevent the union of the surfaces. See **ACTOGENON'S SOLDERING.**

Hydrogen is often used also for the reduction of metals from their different combinations; the reduction is effected by passing a current of hydrogen over the compounds heated to redness.

Its use in reducing ores on the large scale has been proposed, but as yet not found practicable.—H. K. B.

HYDROMETER. An instrument for ascertaining the specific gravities of liquids. Baume's hydrometer, which is much used in France, and other countries of the continent of Europe, when plunged in pure water, at the temperature of 55° Fahr., marks 0 upon its scale; in a solution containing 15 per cent. of common salt (the scale of soda), and 85 of water by weight, it marks 150; so that each degree is meant to indicate a density corresponding to one per cent. of that salt. See **ALCOHOLMETER** and **ASTROMETER.**

HYDROPHANE. A variety of opal which readily imbibes water, and when immersed it becomes transparent, though opaque when dry. It is found in Hungary, and in Ireland, near the Giant's Causeway, and at Croaghragh, Ballywaden.

HYDROSTATICS. The science which treats of the equilibrium of fluids, and of the pressure exerted by them.

In the engineering arrangements by which water is supplied to towns, hydrostatics becomes of the utmost importance. The highest possible level is obtained for the

reservoir, and from this a series of pipes is arranged through all the streets and houses. The bottom of the water is to 100 to 150 feet below the level, and hence all the pipes are filled with water, and in all such as are below the level of the water in the reservoir a pressure upward is exerted equal to the height of the reservoir above that point; and if a hole is put in the pipe, the water jets out with a force equal to this pressure. In the highest houses, the water perhaps only finds its level, and flows out without pressure quickly. See WATKIN PRINCIPLES OF HYDRAULIC ENGINEERING.

HYDROSULPHURETS. Chemical compounds of bases with sulphuretted hydrogen, or hydrosulphuric acid.

HYDROXIA COURBAIL. A tree growing in South America, from which the resin is obtained.

HYPEROXYMURIATES. The old and incorrect name of CHLORATES.

HYPOCHLORIC ACID. HOCl , Eq. 67.5. When finely powdered chloride of potash is gradually mixed in a paste with strong sulphuric acid, and heated in a bath of alcohol and water, a yellow gas is discharged which is this hypochloric acid, or the peroxide of chlorine. Although of much interest as a chemical compound, it has no use in the arts. See *Watts's Chemical Dictionary*.

HYPOCHLOROUS ACID. HOCl , Eq. 67.5. This acid is best obtained by dissolving red oxide of mercury finely divided through twelve times its weight of water, which is introduced into a bottle containing chlorine, and agitated until the gas is absorbed. An oxide of mercury is formed, which is removed by subsidence. The weak fluid obtained is put into a flask, and heated in a water bath, when the evolved gas is collected in a smaller portion of water, which becomes a pure solution of hypochlorous acid.

The salts are termed hypochlorites. See CHLORINE and BLEACHING.

HYPOSULPHATES. Saline compounds formed by the union of hyposulphuric acid with bases.

HYPOSULPHITES. Saline compounds formed by the union of hyposulphurous acid with bases.

Hyposulphate of Soda. The salts of the hyposulphuric acid are obtained from the hyposulphate of manganese, which is itself thus prepared: finely divided binoxide of manganese is collected in water, artificially cooled, and a stream of sulphurous acid passed through it. The binoxide gives up half its oxygen, becoming protoxide, which unites with the hyposulphuric acid which is formed, producing the soluble hyposulphate of manganese, which is separated from the excess of binoxide by filtration.

The following equation represents the reaction:—

If the temperature were allowed to rise, sulphuric acid would be formed, and not hyposulphuric:—

The hyposulphuric acid, unlike the hyposulphurous acid, may be obtained in the free state, and its solution permits even of being evaporated *in vacuo*, until it acquires the density of 1.347; but if carried further, it is decomposed into sulphuric and sulphurous acids.

The acid is obtained in the free state by adding baryta water to the hyposulphate of manganese: the soluble hyposulphate of baryta, filtered from the oxide of manganese, and precipitated exactly by the cautious addition of sulphuric acid, and filtered from the precipitate of sulphate of baryta, yields the pure solution of the acid, which may be evaporated *in vacuo*, as above stated.

It has no odour, but a very sour taste.

The hyposulphate of soda may be made directly from the manganese salt or from the free acid.

All the hyposulphates are soluble; they have not as yet met with any commercial application.

Hyposulphite of Soda. This salt, now so extensively used for photographic purposes, was first introduced by Sir J. Herschel. It may easily be prepared by the following process: viz. by transmitting through a solution of sulphide of sodium (prepared by fusing together in a covered crucible equal weights of carbonate of soda, and flowers of sulphur), a stream of sulphurous acid until it ceases to be absorbed; the liquid is then filtered and evaporated, when the hyposulphite of soda ($\text{NaO.SO}^2 + 5\text{H}_2\text{O}$) crystallizes out.

Another and perhaps better process consists in digesting a solution of sulphite of soda on flowers of sulphur. The sulphur gradually dissolves, forming a colourless

substance, which yields on evaporation crystals of hypophosphite of soda; the reaction being shown by the following equation:—

The baryta salt may be obtained in small brilliant crystals, by mixing an intimate mixture of chloride of barium and hypophosphite of soda.

The hypophosphorous acid is incapable of existing in the free state, for almost immediately on the addition of an acid to the solution of its salts, it is decomposed into sulphurous acid, with liberation of sulphur, ($\text{SO}^{\text{O}} = \text{SO}^{\text{O}} + \text{S}$).

The soluble hypophosphites have the power, in a marked degree, of dissolving certain salts of silver, as the chloride, iodide, &c., which are insoluble in water; forming with them soluble salts, whose solutions possess an intensely sweet taste, although the solutions of the hypophosphites alone possess a disagreeable bitter taste.

From the above reaction arises the principal value of the hypophosphite of soda, which is used by the photographer to dissolve off from the photograph, after the action of the light on it, all the undecomposed silver salt, thus preventing the further action of the light on the picture.

A double hypophosphite of soda and gold is used for gilding the daguerreotype plate, and for colouring the positive prints obtained in photographic printing. This double salt may be obtained in a state of purity, by mixing concentrated solutions of 1 part of chloride of gold, and 2 parts of hypophosphite of soda; by the addition of alcohol it is precipitated; the precipitate must be re-dissolved in a small quantity of water, and again precipitated by alcohol. Its formation is explained by the following equation:—

HYSON. A green tea. See TEA.

I.

IBEX. An animal of the goat kind, the hair of which is esteemed for some kinds of manufacture.

ICEHOUSE. (*Glaicere*, Fr; *Eishaus*, Germ.) Under the article FRIGIDITY, the different artificial methods of producing cold are enumerated. But for the uses of common life, in these climates, the most economical and convenient means of refrigeration in hot weather may be procured by laying up a store of ice in winter, in such circumstances as will preserve it solid during summer.

An icehouse should not be regarded as an object of mere luxury; in the southern countries of Europe it is considered among people in easy circumstances as an indispensable appendage to a country mansion. During the dog days, especially at those periods and in those districts where the sirocco blows, a lassitude and torpor of mind and body supervene, with indigestion or total loss of appetite, and sometimes dysenteries, which are obviously occasioned by the excess of heat, and are to be prevented or counteracted chiefly by the use of cold beverages. By giving tone to the stomach, iced drinks immediately restore the functions of the nervous and muscular systems when they are languid; while they enable persons in health to endure without much inconvenience an atmosphere so close and sultry as would be intolerable without this remedy. Icehouses, moreover, afford to country gentlemen a great advantage in enabling them to preserve their fish, butcher meat, dead poultry, and game, which would otherwise, in particular states of the weather, immediately spoil. Considering at how little expense and trouble an icehouse can be constructed, it is surprising that any respectable habitation in the country should not have one attached to it. The simplest and most scientific form is a double cone, that is, two cones joined base to base; the one being of stones or brick-work, sunk under ground, with its apex at the bottom, into which the ice is rammed; the other being a conical roof of carpentry covered with thatch, and pointed at top. The entrance should be placed always on the north side; it should consist of a corridor or porch with double doors, and be screened from the sunbeams by a small shrubbery. Such are the principles upon which an icehouse should be formed; but they will be better understood by the following explanation and figure.

A dry and sandy soil if possible should be selected; and here a cavity is to be dug about 16 feet in diameter, terminating below like the point of a sugar loaf. Its

ordinary depth for a family may be about 24 feet; but the larger the dimensions are, the longer will it preserve the ice, provided it be fixed. In digging, the workman should slope the ground progressively towards the axis of the cone, to prevent the earth falling in. This conical slope should be faced with brick or stone work about one foot thick, and jointed with lime mortar, so as to be air and water-tight. A well is to be excavated, at the bottom 3 feet wide and 4 deep, covered at top with an iron grating for supporting the ice, and letting the water drain away.

The upper cone may likewise be built of brick-work, and covered with thatch; such a roof would prove the most durable. This is the construction shown in fig. 244. Whatever kind of roof be preferred, there must be left in it an oblong passage into the interior. This porch should face the north, and be at least 4 feet long by $2\frac{1}{2}$ feet wide; and properly closed by a well fitted door at each end. All round the bottom of this conical cover, a gutter should be placed to carry off the rain to a distance from the ice-house, and prevent the circumjacent ground from getting soaked with moisture.

Fig. 245 shows the section of a well-constructed ice-house. Under the ice chamber A the ice is rammed till the space B C is the grate of the drain-pipe. The portion D E is built in brick or stone; the base of the ice chamber slopes inward towards the centre at C. The upper part of the brick-work A A is a little way below the level of the ground. The wooden framework F F F forms the roof, and is covered with thick thatch. G H is the wooden work of the door. At K the back is seen for lifting up a charge of ice, by means of the cord J passing over the pulley M, which enables the servant to raise it easily.

The ice-house should have no window to admit light; but be, so to speak, hermetically sealed in every joint, except at its escapement, which may terminate in a water trap to prevent circulation of air. A clear day should be selected for charging the ice-house; but before beginning to fill, a quantity of long dry straw should be laid on the bottom crosswise; and as the ice is progressively introduced, straw is to be spread against the conical sides, to prevent the ice from coming into contact with the brick or stone work. The more firmly compacted the ice is, the better does it keep; with which view it should be broken into pieces with mallets before being thrown in. No layers of straw should be stratified among the ice, for they would make its body porous. Some persons recommend to pour in a little water with the successive layers of ice, in order to fill up its small crevices, and convert the whole into one mass.

Over the top layer a thick bed of straw should be spread, which is to be covered with boards surmounted with heavy stones, to close up the interstices in the straw. The inner and outer door should never be opened at once; but the one should always be shut before the other is opened. Dry snow will rammed keeps equally well with hard ice, if care be taken to leave no cavities in the mass, and to secure its compactness by sprinkling a little water upon the successive charges.

To facilitate the extraction of the ice, a ladder is set up against its sloping wall at one side of the door, and left there during the season.

ICE BY THE RED-HOT PROCESS. See SENEZIOIAL STATE.

ICE-PRODUCING MACHINE. See FAREZING.

ICELAND MOSS (*Lichen d'Islande*, Fr.; *Flechtel Isl.*, Germ.) is a lichen, the *Cetraria Islandica*, which contains a substance soluble in hot water, but forming a jelly when it cools, styled *lichenine* by M. Guerin. This moss is called in the Pharmacopœia *Lichen Islandicus*. It appears to have derived its name from the circumstance that the Icelanders first discovered its medicinal qualities. Lichenine is prepared by extracting first of all from the plant a bitter colouring matter, by digesting 1 pound of it in 16 pounds of cold water containing one ounce of pearl-ash; then draining the lichen, calcinating with cold water, and boiling it in 9 pounds of boiling water, till 3 pounds be evaporated. The jelly which forms, upon cooling the filtered solution, is dark coloured, but, being dried and redissolved in hot water, it becomes clear and colourless. Lichenine consists of 39.33 carbon, 7.24 hydrogen, and 53.43 oxygen. The mucilage of Iceland moss is preferred in Germany to common paste for dressing

the way of water in the lamp, because it remains dark, being in hydrostatic equilibrium. It is also covered with the glass for saving paper in the vat. The normal pressure was previously obtained from the barometer, and the corrected density.

HOLLAND SPAR. Crystals of Iceland spar, of which the most beautiful specimens are brought from Iceland. These are particularly for their double refraction, and besides the crystal is sometimes polished double refracting spar.

IDWALL-STOSE. A quality of Wax from Idwal. It is obtained from the older and better kinds of the Swedish district.

HUXANTHINE. A substance which might be employed for dyeing yellow, derived from the leaves of the common holly.

ILLUMINATION. The science of determining the relative values of different sources of illuminating power.

It is one of the most important that we should be enabled with facility to determine the relative value of the light which we receive from artificial sources. The only way in which this can be effected, is by comparing with some standard source of light the illuminating power of a candle. Dr. Fire, who was an original occasion to induce us to direct his attention to the subject of illumination, proposed many very important and exact experiments to some of which it appears important that we should direct particular attention. All the original papers in the work of illumination, many parts are now obsolete, but as much of it is still of considerable practical value, the following selection have been made, all such being distinguished by Dr. Fire's name. After many experiments to determine a standard, Dr. Fire says:—

"After comparing lights of many kinds, I find every reason to conclude that a large wax candle of three to the pound, either long or short, that is, either 12 or 15 inches in length, as manufactured by one of the great wax-candle makers, and furnished with a wick containing 27 or 28 threads of the best Turkey cotton, is capable of furnishing a most uniform, or nearly invariable standard of illumination. It affords one-tenth of the light emitted by one of the Argand lamps of the Troying House, and one-eleventh of the light of my mechanical lamp, when such lamp is made to burn with its maximum flame, short of smoking."

Dr. Fire, however, for many of his determinations employed the French mechanical lamp, known as Carcel's lamp; and in connexion with this the following remarks occur:—

"Mr. Samuel Parker, long advantageously known to the public for his economical and portable lamp, as well as other inventions subservient to domestic comfort, having obtained a patent for a new lamp, in which the oil is heated by a very simple contrivance, in the operation of any desired degree, being arrived at the work, I instituted an extensive series of experiments to determine its value in the production of light, and consumption of oil, compared to the value of other lamps, as well as candles, in these respects."

In fig. 265 A, A, B, C, is a section of the cylinder which constitutes the burner; the oil being contained between the inner and outer cylinders, and receiving heat from the flame of the lamp which passes up through the inner cylinder, and is reverberated more or less against its sides by the top of the metal chimney being notched and bent back. D is a slide-valve which is opened to allow the oil to descend to the wick, and is shut when the burner is to be separated from the pipe of supply, at E, for the purpose of recharging it with oil. The flame is not fed, not by raising or lowering the wick, as in common lamps, but by raising or lowering the bell-mouthed glass chimney which rises at its bottom on three points, and is moved by means of the rack-work mechanism. The burner cylinder is of the size of a pint imperial, and should be made entirely full before lighting the lamp, so as to leave no air in the burner, which, by its expansion with the heat, would otherwise cause an overflow of the oil.

The following arrangement was adopted in these experiments for determining the relative illumination of the different lights. Having trimmed, with every precaution, my French mechanical lamp, and charged it with sperm oil, I placed it upon an oblong table, at a distance of 10 feet from a wall, on which a white sheet of paper was stuck. One of Mr. Parker's hot-oil lamps, charged with a quantity of the same oil, was placed upon the same table; and each being made to burn with its maximum brilliancy, short of smoking, the relative illumination of the two lamps was determined by the well-known method of the comparison of shadows; a wire a few inches long, and of the thickness of a crow-quill, being found suitable for enabling the eye to estimate very nicely the shade of the intercepted light. It was observed in numerous trials, both by my own eyes and those of others, that when one of the lamps was shifted half an inch nearer to or further from the paper screen, it caused a perceptible difference in the tint of the shadow. Professor Wheatstone kindly enabled me to verify the precision of the above method of shadows, by employing in some of the experi-

ments, a photometer of his own invention, in which the relative brightness of the two lights was determined by the relative brightness of the opposite sides of a revolving silvered ball, illuminated by them.

1. The mechanical lamp was furnished with a glass chimney 1.3 inch in diameter at the base, and 1.2 at top; the wide bottom part was 1.9 inch long, and the narrow upper part 6 in. hrs. When placed at a distance of 10 feet from the wall its light there may be estimated as the square of the number, or 100. In the first series of experiments, when burning with its maximum flame, with occasional flickerings of smoke, it emitted a light equal to that of 11 wax candles, and consumed 913 grains of oil per hour. The sperm oil was quite pure, having a specific gravity of 0.784 compared to water at 100°. In a subsequent series of experiments, when its light was less flickering, and equal only to that of 10 wax candles, it consumed only 515 grains, or 0.1164 of a lb. per hour. If we multiply this number into the price of the oil (82. per gallon) per lb. 11d., the product 1.2554d. will represent the relative cost of this illumination, estimated at 100.

2. The hot-oil lamp burns with a much steadier flame than the mechanical, which must be ascribed in no small degree to the rounded shape of the bell-mouthed glass chimney, whereby the air is brought progressively closer and closer into contact with the outer surface of the flame, without being furiously dashed against it, as it is by the rectangular shoulder of the common contracted chimney. When charged with sperm oil, and made to burn with its maximum flame, this lamp required to be placed one foot further from the screen than the mechanical lamp, in order that its shadow should have the same depth of tint. Hence, its relative illumination was, in that case, as the square of 11 to the square of 12, or as 121 to 100. Yet its consumption of oil was only 694 grains, or somewhat less than 0.1 of a lb. per hour. Had its light been reduced to 100, it would have consumed only 576 grains per hour, or .082 of a lb. If we multiply this number by 11d., the product 0.9024d. will represent the relative cost of 100 of this illumination.

3. The hot-oil lamp being charged with the southern whale oil, of specific gravity 0.776, at 72. 6d. per gallon, or 5.4. per lb., when burning with its maximum flame, required to be placed 9 feet and 1 inch from the screen to drop the same tint of shadow upon it as the flames of the other two lamps did at 10 and 11 feet with the sperm oil. The square of 9 feet and 1 inch = 82 is the relative illumination of the hot-oil lamp

with the southern wax, 22. It consumed 700 grs. a, or 0.111 of a pound per hour, but had it given 100 of light it would have consumed 911 grs., or 0.14 of a pound, which number being multiplied by its price 3d., the product 423.3d. will represent the relative cost of 100 of this light.

4. A hot-oil lamp charged with sperm oil of sp. gr. = 0.914, at 2s. 6d. per gallon, or 74d. per lb., when burning with an average flame extended to be placed at 9 feet 6 inches, to obtain the standard test of flame upon the screen. It consumed 700 grains per hour. The square of $9\frac{1}{2}$ feet is 90.25, which is the relative intensity of the light of this lamp. Had it consumed a light = 100, it would have consumed 914 grains, or 0.12 of a pound per hour—this number multiplied by the price per pound, gives the product 0.012 as the relative cost of 100 of this light.

5. A hot-oil lamp charged with 17° and 60° (a mixture of oil of olive and of sperm gravity 0.923), at 1s. 6d. per gallon, or 74d. per lb., had it to be placed 9 feet from the screen, it consumed 1063 grains per hour. Had its light been 1000 of 0.100, the illumination would have been 1277 grains, or 0.143 of a pound per hour; which number multiplied by its price per pound, the product 1.013d. will represent the cost of 100 of this illumination.

6. In comparing the consumption of French angular lamp in general use with the mechanical lamp, it was found to give about one-half the light, and to consume two thirds of the oil of the mechanical lamp.

7. Wax candles from some of the most eminent wax-chandlers of the metropolis were next subjected to experiment; and it is very remarkable that, whether they were three, four, or six in the pound, each afforded very nearly the same quantity of light, for each required to be placed at a distance of 3 feet from the screen to afford a shadow of the same tint as that dropped from the mechanical lamp, estimated at 100. The consumption of a genuine wax candle, in still air, is, upon an average of many experiments, 123 grains per hour, but as it affords only $\frac{1}{11}$ of the light of the mechanical lamp, 11 times 123 = 1353 grains, or 0.1064 of a pound is the quantity that would need to be consumed to produce a light equal to that of the said lamp. If we multiply that number by the price of the candles per lb. = 30d., the product = 325.32d. is the cost of 100 of illumination by wax. A wax candle, three in the pound (short), is one inch in diameter, 13 inches in length, and contains 27 or 28 threads, each about $\frac{1}{16}$ of an inch in diameter. But the quality of the wick depends upon the capillarity of the cotton fibrils, which is said to be greatest in the Turkey cotton, and hence the wicks for the best wax candles are always made with cotton yarn imported from the Levant. A wax candle, three in the pound (long), is $\frac{1}{2}$ of an inch in diameter, 15 inches long, and has 26 threads in its wick. A wax candle, six in the pound, is 2 inches long, $\frac{1}{2}$ of an inch in diameter, and has 22 threads in its wick. The light of this candle may be reckoned to be, at most, about $\frac{1}{11}$ less than that of the three in the pound. A well-made short three burns with surprising regularity in still air, being at the rate of an inch in an hour and a half, so that the whole candle will last 15 hours. A long three will last as long, and a six about 9 $\frac{1}{2}$ hours. Sp. gr. of wax = 0.960.

8. A spermaceti candle, three in the pound, is $\frac{1}{2}$ of an inch in diameter, 15 inches long, and has a plaited wick, instead of the parallel threads of a wax candle. The same candles four in the pound, are $\frac{1}{2}$ of an inch in diameter, and 15 $\frac{1}{2}$ inches long. Each gives very nearly the same quantity of light as the corresponding wax candles; viz. $\frac{1}{11}$ of the light of the above mechanical lamp, and consumes 142 grains per hour. Multiplying the last number by 11, the product, 1562 grains = 0.223 of a pound, would be the consumption of spermaceti requisite to give 100 of illumination. Multiplying the last number by 24d., the price of the candles per pound, the product, 5.332d. is the relative cost of 100 of this illumination.

9. Stearic acid candles, commonly called German wax, consume 164.5 grains, or 0.024 of a pound per hour, when emitting the same light as the standard wax candle. Multiplying the latter number by 11, and by 16d. (the price of the candles per lb.), the product 4.224d. will represent the relative cost of 100 of this illumination.

10. Tallow candles: moulds, short three, 1 inch in diameter, and 13 $\frac{1}{2}$ in length; ditto long three, $\frac{1}{2}$ of an inch in diameter, and 15 in length; ditto long four, $\frac{1}{2}$ of an inch in diameter, and 15 $\frac{1}{2}$ in length. Each of these candles burns with a most uncertain light, which varies from $\frac{1}{12}$ to $\frac{1}{10}$ of the light of the mechanical lamp—the average may be taken at $\frac{1}{11}$. The three consumes each 144 grains, or 0.2 of a pound, per hour; which number, multiplied by 14, and by 9d. (the price per pound), gives the product 2.52d. for the relative cost of 100 of this illumination.

11. Palmer's spreading wick candles. Distance from the screen 3 feet 4 inches, with a shadow equal to the standard. Consumption of tallow per hour 232.5 grains, or 0.0332 of a pound. The square of 3 feet 4 inches = 119 is the relative illumination of this candle = 119 : 0.0332 :: 100 : 0.29 = 10d. = 11.9 is the relative cost of this illumination.

12. Cocoa-nut stearine candles consumed each 168 grains per hour, and emitted a light equal to $\frac{1}{16}$ of the standard flame. Multiplying 168 by 16, the product 2,708 grains, or 0.441 of a lb., is the quantity which would be consumed per hour to afford a light equal to 1 lb. And 0.441 multiplied by 10d., the price per lb., gives the product 4.41d. as the cost of 100 of this illumination per hour.

10. A gas Argand London lamp, of 15 lbs., a circle of $\frac{7}{8}$ of an inch in diam. & r. with a flame 3 inches long, afforded a light 78% compared to the mechanical lamp. Assuming the light of the mechanical lamp as before at 100, that of the best lamp is 121, and that of the above gas flame 78.7, or in round numbers 80, and the common New-A lamp in general was 50.

Collecting the preceding results, we shall have the following tabular view of the cost per hour of an illumination equal to that of the mechanical lamp, reckoned 100, or that of a tallow wax candle, three to the pound.

TABLE of COST per HOUR of ONE HUNDRED of ILLUMINATION.

	Price	Price
1. Parker's hot-oil lamp, with southern whale oil	- 0 18 75 or about	1 1/2
2. Mather's lamp or Carcel lamp, with sperm oil	- 1 3 00	1 1/2
3. Parker's hot-oil lamp, with sperm oil	- 0 90	1
4. Ditto ditto common olive oil	- 0 90	1
5. Ditto ditto common nut oil or oil	- 1 00	1
6. French lamp in general use, with sperm oil	- 1 75	1 1/2
7. Wax candles	- 3 00	6
8. Sperm candles	- 5 00	5
9. German wax (Stearic acid) ditto	- 4 25	4
10. Palmer's spreading wick candles	- 2 00	2
11. Tallow (mould) candles	- 2 20	2
12. Common tallow candles	- 4 00	4

The following table contains, according to Peclot, the illuminating powers of different candles, and their consumption of material in an hour: the light emitted by a French Argand lamp, consuming 42 grammes (= 42 · 15 grains) in an hour, being called unity.

	Intensity of l. ghd.	Consumpt — per Hour.
Tallow candles 6 in lb	10'66	8'31
Stearine, or pressed tallow, 8 in lb. . . .	8'74	7'11
, 5 in lb. . . .	7'50	7'42
Wax candles, 5 in lb.	13'61	8'71
Spermaceti, 5 in lb.	14'40	8'92
Stearic acid, commonly called stearine, 5 in lb.	14'40	9'33

The following table shows the economical ratios of the candles, where the second column gives the quantity of material in grammes which is requisite to produce as much light as the Carcel lamp.—

	Quantity of Material.	Pipes per Kilogramme.	Cost of 1 foot per Hour.
Tallow candle, 6 per lb. . .	70.35	1 f. 40 c.	9.8 c.
, 8 per lb. . .	85.72	1 f. 40 c.	12.0 c.
Pressed tallow, 5 per lb. . .	94.93	2 f. 40 c.	27.7 c.
Wax candle, 5 per lb. . .	64.04	2 f. 40 c.	48.6 c.
Spermaceti ditto, 5 per lb. . .	61.91	2 f. 00 c.	47.8 c.
Stearine, 5 per lb. . .	65.24	6 f.	57.1 c.

These results may be compared with mine given above. A kilogramme, or 1000 grammes = 15,440 grains = 2 1/2 lb. avoirdupois. — *Urr.*

The rule observed in the determination of these questions of illuminating power, is, according to the laws of optics, that the sum of the luminous rays from any source is inversely as the square of the distance from their source.

"The numerical estimation of the degrees of intensity of light constitutes that branch of optics which is termed PHOTOMETRY.

"If light be a material emanation, a thing covered in minute points, be in all directions, it is plain that the same quantity which is diffused over the surface of a sphere, concentric with the luminous points, if it extend to its centre, will uniformly be diffused over larger and larger concentric spherical surfaces; and then its intensity, or the number of rays which fall on a given space, in each will be inversely as the whole surfaces over which it is diffused; that is, inversely as the square of their radii, or of their distances from the source of light. . . . Let a screen be placed behind an opaque screen, full of small equal and similar holes: the light will shine through them, and be concentrated in all other parts, forming a parabolical bundle of rays, having the ends in the common vertex. If a sheet of white paper be placed behind this, it will be spotted over with small luminous specks, disposed exactly as the holes in the screen. Suppose the holes so small, their number so great, and the eye so distant from the paper, that it cannot distinguish the individual specks, it will still receive a general impression of brightness; the paper will appear illuminated, and present a mottled appearance, which, however, will grow more uniform as the holes are smaller and closer, and the eye more distant, and if extremely so, the paper will appear uniformly bright. Now if every alternate hole in the screen be covered, the paper will manifestly receive only half the light, and will therefore be only half as bright as before, and *inter se* pass, so the degree of illumination is proportional to the number of holes in the screen, or to the number of equally illuminated specks on the surface; i. e. if the speck be itself divided in size, and infinitely increased in number to number to the number of rays which fall on it from the original source of light." (*Herschel*.)

Recommending Sir John Herschel proceeds and establishes the following definitions—
The real intrinsic brightness of a luminous object is the intensity of the light of each physical point in its surface.

The apparent intrinsic brightness of any object or luminary is the degree of illumination of its image or picture at the bottom of the eye.

The absolute light of a luminary is the sum of the areas of its elementary portions, each multiplied by its own intrinsic brightness.

The apparent light of an object is the total quantity of light which enters our eyes from it, however distributed on the retina.

Various instruments, called *photometers*, have been devised to measure the illuminating power of any body; these are, all of them, more or less defective, and the results which we obtain with the best of them are merely comparative with each other.

Bouguer's photometer consisted of two surfaces of white paper, of exactly equal size and reflective power, cut from the same piece in contact; these are illuminated, the one by the light whose illuminating power is to be measured; and the other by a light whose intensity can be varied at pleasure by an increase of distance, and can therefore be exactly estimated. The variable light is to be removed or approached, till the two surfaces are judged to be equally bright, when the distances of the luminaries being measured, or otherwise allowed for, the measure required is ascertained.

Newford's photometer. Before a screen of white paper, in a darkened room, is placed a blackened cylindrical stick, and the two lights to be compared are so placed that two shadows are thrown upon the screen side by side, with an interval between them about equal in breadth to either shadow. The brighter flame must then be removed, or the feather brought nearer to the screen, till the two shadows appear of equal intensity, when their distances from the lights must be measured, and their total illuminating powers will be in the direct ratio of the squares of the distances.

Ritchie's photometer consists of a rectangular box, about an inch and a half or two inches square, open at two ends. It is blackened within to absorb the extraneous light. Within, inclined at angles of 45° to its axis, are placed two rectangular pieces of plain looking-glass, cut from one and the same rectangular strip; these are fastened so as to meet in the middle of a narrow slit, about an inch long, and an eighth of an inch broad, which is covered with a slip of fine tissue or oiled paper, and a blackened card prevents the reflected images from mingling. If we would compare two lights, they must be placed at such a distance from each other, and from the instrument between them, that the light from every part of each shall fall on the reflector next it, and be reflected to the corresponding portion of the paper. The instrument is then to be moved nearer to the one or the other, till the paper on either side of the division appears equally illuminated. When the lights are thus exactly equalised, it is clear that the total illuminating powers of the luminaries are directly as the squares of their distances from the middle of the instrument.

Wheatstone's photometer is a small sphere with a reflecting surface, which being placed between the two lights, each light is seen on it by the spectator, the two being reflected from different points of the sphere's surface. By an ingenious but simple

mechanical contrivance, a rapid motion is communicated to the ball, and by the principle of the persistence of impressions, the spectator immediately sees two curved curves of different brightness. The lighter spot is removed until these curves seem of the same brightness, and the intensities of the luminous points are then as the squares of the distances.

Hansen's photometer consists of a sheet of cream-colored letter paper, rendered transparent over a portion of the surface by a mixture of spermaceti and refined naphtha, which is solid at room temperatures, but becomes liquid on the application of a very gentle heat. The mixture is liquefied and painted over the paper with a brush, leaving a round spot of the size of half a crown in the centre uncovered. When a light is placed on one side of the paper a dark spot is observed on the uncovered portion. When another light is placed on the other side of the paper, the spot is still distinctly visible, if the distance of the light is such that the reflected portion from the paper be either of greater or of less intensity than that transmitted. When the paper is so situated between the two flames that the transmitted and reflected light are of the same intensity, the uncovered spot is no longer visible.

It will be evident from these descriptions that it is possible only, by any of these contrivances, to compare one light with another; there is not any arrangement by which we are enabled to express absolutely the illuminating power. Upon the principle of comparison, and comparatively, the following tables have been constructed by the relative experimental results. The observations of Pictet have been already given. The following comparative view of wax and stearine candles manufactured in Berlin, which have been deduced from the observations of Scherlath, is of much value.

Kind of candle, and whence obtained.	Height of flame to centre of light	Consumption in one hour, in grammes	Illuminating power
Common wax candles, of Taubhanser - - -	4's	103.5	83.20
	6's	91.0	83.20
	8's	100.0	100.00
Wax candles, of Walker - -	4's	133.7	92.66
	6's	140.3	97.69
	8's	113.1	104.1
Stearine candles, of Motard -	4's	117.4	81.74
	6's	111.8	78.23
	8's	121.0	100.7
Stearine candles, of Magniet and Oelmichen - -	4's	120.5	86.11
	6's	122.7	92.66
	8's	123.0	96.54
Stearine candles from the same makers - - -	4's	118.1	85.86
	6's	145.0	100.00
	8's	124.5	92.67
Candles made from palm oil -	4's	115.3	82.56
	6's	115.3	82.56
	8's	167.3	113.70

These results show us that the mean illuminating power of wax and stearine candles is nearly the same.

The illuminating power of gases and of gas burners will be found in the article COAL GAS.

IMPERMEABLE, is the epithet given to any kind of textile fabric, rendered water-proof by one or other of the following substances;—

1. Linseed oil to which a drying quality has been communicated by boiling with litharge or sugar of lead, &c.

2. The same oil holding in solution a little caoutchouc.

3. A varnish made by dissolving caoutchouc in rectified petroleum or naphtha, applied between two surfaces of cloth, as described under Macintosh's patent. See CAOUTCHOUC.

4. Vegetable or mineral pitch, applied hot with a brush, as in making tarpauling for covering goods in ships.

5. A solution of soap worked into cloth, and decomposed in it by the action of a solution of alum; whence results a mixture of acid, fats, and alumina, which imbricate itself among all the woolly filaments, fills their interstices, and prevents the passage of water.

6. A solution of glue or isinglass, introduced into a stuff, and then acted upon by a clear infusion of galls, whereby the fibres get impregnated with an insoluble, impermeable, pulverulent leather.

7. Plaster work and plastering, to be by using artificial or natural asphaltum with it.

INCUBATION, ARTIFICIAL. The Egyptians have from time immemorial been accustomed to hatch eggs by artificial warmth, which the art of heat is peculiarly adapted to. M. de Réaumur published in France, about a century and a half ago, an observation upon this subject, but M. Bonnemaison was the first person who studied with determination all the circumstances of artificial incubation, and illustrated the process continually upon the incubation of water for duck as 1777 he communicated to the Academy of Sciences an interesting fact, which he had noticed, and the method employed by ducks to keep their eggs warm, and he communicated the process to the French nation; he furnished the Parisian market with excellent poultry at a period of the year when the farmers had ceased to supply it. His establishment was ruined at that disastrous era, and he never has ever since been compensated or connected with similar care. His apparatus for warming is based upon the fact that it was founded upon the principle of the circulation of hot water, by the constant motions of its particles, in a returning series of currents; upon a subject afterwards illustrated in the experimental researches of Count Rumford. It has of late years been introduced as a novelty into this country, and applied to warm the apartments of many public and private buildings. The following details will prove that the theory and practice of hot water circulation were as perfectly understood by M. Bonnemaison fifty years ago, as they are at the present day. They were then publicly exhibited at his residence in Paris, and were afterwards communicated to the world at large in the interesting article of the *Encyclopédie Technologique*, intitled *Incubation artificielle*, under the head of *Repositaire de Température*.

The apparatus of M. Bonnemaison consisted 1. of a boiler and pipes for the circulation of water; 2. of a regulator calculated to maintain an equal temperature; 3. of a stove-apartment, heated constantly to the degree best fitted for incubation, which he called the *hatching pit*. He attached to one side a passage or orifice for the chickens during a few days after hatching.

The boiler is represented in vertical section and ground plan, in figs. 987 and 988. It is composed of a double cylinder of copper or cast iron, *b*, having a grate *b* (see plan), an ashpit at *d* (see plan). The water occupies the shaded space *c, c, h, g, g, e, e*, are five vertical flues for conducting the burnt air and smoke, which first rise in the two exterior flues *e, e*, then descend in the two exterior flues *g, g*, and finally re-ascend through the pipes *e, e*, in the central flue *h*. During this upwards and downwards circulation, as shown by the arrows in the section, the products of combustion are made to impart nearly the whole of their heat to the water by which they are surrounded. At the commencement, some burning paper or wood shavings are inserted at the orifice *m*, to establish a draught in this circulation chimney. The air is admitted into the ashpit at the side, in regulated quantities, through a small square door, movable round a rod which runs horizontally along its middle line. This swing valve is acted upon by an expanding bar (see **HEAT REGULATOR**), which opens it more or less, according to the temperature of the stove apartment in which the eggs are placed.

u is the upper orifice of the boiler, by which the hotter and consequently lighter particles of the water continually ascend, and are replaced by the cooled particles, which enter the boiler near its base, as shown in fig. 989 at *a*. If to farther details relative to the boiler it is needless to enter; for though its form, as designed by M. Bonnemaison, is excellent and most economical of heat for a charcoal fire, it would not suit now of petroleum, on account of the obstruction to the pipes which would soon be caused by its soot.

In fig. 989 the boiler is shown at *a*, with the valve which regulates the air flow of the ashpit. *n* is a stopcock for modifying the opening by which the hotter particles of water ascend; *o* is the water pipe of communication, having the heating pipe of distribution attached between *e, e*, which thence passes backwards and forwards with a very slight slope from the horizontal direction, till it reaches the passage *q, q, r, q*. It traverses this apartment, and returns by *a, a* to the orifice of the boiler *u*, where it turns vertically downwards, and descends to nearly the bottom of the boiler, discharging at that point the cooled and therefore denser particles of water to replace those which continually issue upwards at *u*. *z, z* is a tube surmounted with a funnel for keeping the range of pipes always full of water; and *x* is a siphon orifice for permitting the escape of the disengaged air, which would otherwise be apt to occupy partially the pipes and obstruct the aqueous circulation.

The faster the water gets mixed in the serpent in tubes, the better the circulation will be, because the difference of density between the water at the top and bottom of

the water, which is the cause of its movement, will be greater. *W* represents a small reservoir of water, to supply the required moisture to the heated air, and *T* is the tube which carries it along the trays *M N*, in an atmosphere analogous to that under the body of the hen.

When we wish to hatch eggs with this apparatus, the fire is to be kept up in the boiler, and as soon as the temperature has risen to about 100° F., the eggs are introduced, but only one-twentieth of the whole number intended, upon the first day; next day a like number is laid upon the trays, and thus in succession for twenty days, so that upon the twenty-first day the eggs first placed may be hatched for the most part, and we may obtain daily afterwards an equal number of chicks. In this way regularity of care is established in the rearing of them.

During the first days of incubation, natural as well as artificial, a small portion of the water contained in the egg evaporates by the heat, through the shell, and is replaced by a like quantity of air, which is afterwards useful for the respiration of the animal. If the warm atmosphere surrounding the eggs were very dry, such a portion of the aqueous part of the eggs would evaporate through the pores of the shells as would endanger the future life of the chick in *ovo*. The transpiration from the body of the hen, as she sits upon her eggs, counters to this destination in general; yet in very dry weather many hatching eggs fail from that cause, unless they be placed in moist downy posing straw. The water sources *M N* are therefore essential to success in artificial incubation.

After the chicks are hatched they are transferred into the nursery, *O Q*, on the front of which there is a small grated trough filled with millet seed. Small divisions are made between the levels of successive days, to enable the superintendent to vary their feeding to suit.

In order to supply an establishment of the common kind, where 100 eggs are to be hatched daily, a dozen of hens would be needed, and 150 eggs must be placed under them, as only two-thirds in general succeed. At this rate, 4500 mothers would be required to sit. Now supposing we should collect ten times as many hens, or 45,000, we should not be able to command the above number of chickens, as there is seldom a tenth part of hens in a breeding state. Besides, there would be in this case no fewer than 750 hens every day coming out with a fresh brood of chickens, which would require a regiment of superintendents.

Artificial Incubation by means of Hot Mineral Waters. — This curious process is described very briefly in a letter by M. D'Arceet. The following are extracts from his letter: —

"In June, 1823, I obtained chickens and pigeons at Vichy, by artificial incubation, effected through the means of the thermal waters of that place. In 1827 I went to the baths of Chaudes-Aigues, principally for the purpose of doing the same thing there. Finding the proprietor a sensible man, I succeeded in making a useful application of this source of heat to the production of poultry.

"The advantage of this process may be comprehended, when it is known that the invalids who arrive at Vichy, for instance in the month of May, find chickens only the size of quails; whereas, by this means, they may be readily supplied six months old.

"The good which may be done by establishing artificial incubation in places where hot springs exist, is considerable; it may be introduced into these establishments without at all interfering with the medical treatment of patients, since the hatching would go on in winter, at a time when the baths for other purposes are out of use.

Indigo and Demarmin are both a product called *Indigum*, which is said to have been of a blue colour, though there is little doubt that the purple of which the ancient *Indicum* colours were composed was obtained with our Indian ink. Of course, I may say that it comes from India, and is composed from the same substance, for still, though it is a thick warm reddish, but of a fine mixture of purple and blue, was discovered, and that there is a smaller kind which is found swimming in the dye-makers' water, purple in itself, this being the term for the purple ink. He adds that those who dye with the Indian dye produce a fine or blackish wood, but that the genuine colour may be known by looking at what it gives a beautiful purple colour and is as a small like that of indigo, and for this reason it has been supposed to be the same as the purple. It is now hardly believed that in the purple ink is referred to, and that the ancient kind of indigo was obtained by the same process of the same of indigo, but that it was on the surface of the leaves in which the dyeing was performed. It seems, however, that at that time the colouring matter was not completely separated from the other vegetable matters of the plant as at the present day, when plants are only coloured with wood would bear very little resemblance to the present indigo, but would be a far less value of the preparation, being a pale blue wood. It is probable, however, that at that period the process of manufacturing indigo was a very rude one, and consisted merely in the separation of a portion of the vegetable from the remainder. Even at the present day the nature of some countries, where the article has not attained any high degree of development, produce a variety from indigo-bearing plants which serves the purpose of dyeing blue, though not much resembling indigo in appearance. In Sumatra, for instance, as Marsden informs us, the natives do not make indigo, but use a small plant, and give the roots and branches for some days in water to soak and macerate, then beat it, and work with their hands some *quichme* among it, with leaves of the same plant in a species of fern for fixing the colour, after which they strain it off and use it in the liquid state. On the west coast of Africa the leaves of the indigo plant are pounded into balls, which are then dried in the sun and stored up until they are wanted. These balls, which have a slight bluish tint, may be preserved a long time and be transported to great distances. When they are to be used for dyeing they are broken and reduced to a fine powder. This powder is then mixed with water to which the juice of a certain plant is added, and the liquid is boiled in large earthenware vessels of a conical form, when it assumes a deep blue colour and is then ready for dyeing the fabrics which are plunged into it.

The article known as *indigo* in the middle ages must have been very similar to the indigo of the present day, for though Marco Polo had described the country in which its existence was pointed from the plant, it was for a long time considered as a mineral, and even in the latest part obtained in 1733 by the preparation of indigo in the principality of Hainaut, it was classed among minerals, a mistake of which work was repeated in 1780.

Indigo seems to have been first extensively used in Europe by the Jewish dyers, who introduced it into the dyehouses of Italy. It was not, however, imported in any large quantities until the discovery of the passage round the Cape of Good Hope. At the beginning of the 17th century, the Dutch commenced carrying on an extensive trade with the East, and indigo was one of the articles which they imported in large quantities into European countries. Its use was found to be attended with so many advantages, that the employment of wood for the same purpose was gradually abandoned. The colour produced by it was more brilliant and far cheaper than the blue from wood. On the other hand it was asserted that the goods dyed with indigo faded rapidly, and that the vegetable and other corrosive substances used along with it injured them, after some time to rot. At the same time the exportation of large sums of money in payment for indigo and the rapid decline in the cultivation of wood, which had previously furnished competition to great numbers of people in such as agriculture, fishing, and other kinds of rural pursuits, induced the monarchs of much alarm, that the most effective measures were adopted in order to prevent the use of indigo in dyeing. A decree of the Cortes of Castile at Pinar, in 1577, prohibited, under the severest penalties, the use of indigo, particularly, deer-skin, catgut and otherwise, and the *serf's* dye, for which various other cheaper materials were used instead of wood. This prohibition was renewed in 1582 and 1603. In the year 1608, the Emperor of Spain prohibited the sale and importation into his dominions of all fabrics dyed with indigo or other injurious substances, and threatening with punishment and the confiscation of their goods all persons who should offer for sale any cloth dyed with forbidden and doubtful dyes instead of with the permanent colour of wood. The people of Nuremberg even went so far as to compel their dyers by law

annually to take root, and to supply indigo, and this was continued down to a very recent period, though it was well known that it was not indigenous to the East. In France, the use of indigo was forbidden in 1792, by consequence of an express representation from the states of the province of Languedoc, and this prohibition was afterwards removed several times. But in the well known edict of 1790, in which Custom was separated from the common laws, it was stated that indigo could be used without limit, and in 1797, doors were left at liberty to use indigo alone or to combine it with a mixture of indigo and wool. In England the use of foreign wool is forbidden, and by an act passed by the House of Commons, our doors were not allowed to burn with a single thread of indigo in every dyehouse where they could be found. This act remained in force for nearly a century.

It has been doubted whether the plant which is employed in America for the manufacture of indigo is a native of that country, or whether it was introduced by the Spaniards. It was remarked by the first voyagers on the new continent that the natives coloured their bodies and dyed their stuffs by means of indigenous plants which resembled the indigo plant of Asia. Francisco Fernandez, in the life of the father, says, that this plant grew in a wild state in the West India islands, and that it was cultivated for the purpose of supplying them with a blue pigment. He mentions that it came from the mountains of Mexico, and says, that the Americans were busy drying their hair black. He also, that they made from it a pigment, which they mixed with water and sugar, the same as the red colour of the Indians, and he describes also the method of preparing it. Nevertheless it appears that the Indians of Mexico and Andes really introduced indigo into America by the Spaniards, and were the plants employed by them for the manufacture of indigo in Mexico, Guatemala, and elsewhere, though some of the varieties produced by the influence of the climate and soil are very widely distinguished from the parent stock. The manufacture of indigo was at one time carried on extensively in Central America, and the West India Islands, and these countries formerly supplied the chief portion of the article consumed in Europe. The lodges of Guatemala at the same time exported all others a quarter. It consequently is, however, of the political distribution in America and the great improvements which have been effected in the manufacture of indigo by the several governments of that country in the East, its production in America has diminished very much, and at the present day, the indigo consumed in Europe is derived chiefly from India, and more especially from Bengal, Oude, and Madras. The remainder is imported from Java, Malacca, the Mauritius, and Senegal in the eastern hemisphere, and from Caraccas, Brazil, and Guatemala in the western. The East India and Brazilian indigo is packed in chests, the Guatemala in ox hides, called *semas*. Its quality depends upon the species of the plant, its ripeness, the soil and climate of its growth, and the mode of manufacture.

The plants which are cultivated in the East India, are the *Indigofera tinctoria*, *And. disperma* and *pseudo-tinctoria*. The districts of Kishenagar, Jessore, and Murrabadabad, in Bengal, ranging from 85° to 90° east lat. and 22° to 24° north long., produce the finest indigo. That from the districts about Hardwan and Benares is of a coarser or harsher grain. Tympot, in lat. 26° , yields a tolerably good article. The portion of Bengal most propitious to the cultivation of indigo, lies between the river Hooghly and the main stream of the Ganges. The ground having been ploughed in October, November, or beginning of December, the seed of the indigo plant is sown in the last half of March or beginning of April, while the soil being neither too hot nor too dry, is most propitious to its germination. A light unclouded sky, and a sunshine, with occasional light showers, are most favourable to its growth. From twenty-four to thirty pounds of seeds are required for sowing an acre of land. The plants grow rapidly, and will bear to be cut for the first time at the beginning of July, nay, in some districts, so early as the middle of June. The indications of maturity are the bursting forth of the flower buds, and the expansion of the blossoms, at which period the plant contains most colouring matter. Another indication is taken from the leaves; which, if they break across, when pressed flat, denote a state of maturity. But this character is somewhat fallacious, and depends upon the fertility or richness of the soil. When much rain falls, the plants grow too rapidly, and do not sufficiently elaborate the blue pigment. Bright sunshine is not advantageous to its production. The first cropping of the plants is best; after two months a second is made, but at the present day, planters never undertake a third or fourth.

Two methods are pursued to extract the indigo from the plant; the first effected by fermentation of the fresh leaves and stems; the second, by maceration of the dried leaves.

1. *From the recent leaves.*—In the indigo factories of Bengal, there are two large stone-built cisterns, the bottom of the first being nearly upon a level with the top of the second, in order to allow the liquid contents to be run out of the one into the other.

The upper vat is called the fermenting vat, or the steeping vat; its area is 20 feet square, and its depth 3 feet; the lower vat, called the beating vat, is as broad as the upper, but one third longer. The corners of the floor, as they come from the field, are stratified in the steeping vat, and are tied to within 3 or 4 inches from the beam. In order that the plants, during the fermentation, may not swell and rise out of the vat, boxes of wood and two sets of iron hoops are laid closely over the surface of the plants, after which water is pumped upon them until it stands about 3 or 4 inches from the edge of the vessel. An active fermentation speedily commences, which is, compared with in 14 or 15 hours, a most rapid or shorter, according to the temperature of the air, the prevailing winds, the quality of the water, and the ripeness of the plants. Nine or ten days after the immersion of the plants, the condition of the vat must be examined; frothy bubbles are then seen rising like little pyramids, at first of a white colour, but soon becoming greyish-blue, and then deep purplish-red. The fermentation is at this time violent, the fluid being in constant commotion, and apparently boiling; innumerable bubbles mount to the surface, and a dense copper-coloured crust covers the whole. As long as the liquor is agitated, the fermentation must not be disturbed; but when it becomes more tranquil, the liquor is to be drawn off into the lower vat. If it of the nature of the liquor is not to push the fermentation farther, because the quality of the whole indigo is thereby deteriorated; but rather to cut it short, in which case there is, indeed, a loss of weight, but the article is better. The liquor presents now a greenish yellow colour, which, when the indigo precipitates changes to green. The average temperature of the liquor is commonly 65° Fahr.; its specific gravity at the surface is 1.015; and at the bottom 1.022.

As soon as the liquor has been run into the lower vat, ten men are set to work to beat it with bars or shovels 4 feet long, called *beata*. Paddles which have also been employed for the same purpose. Meanwhile two other labourers clear away the compressed leaves and husks from the surface of the upper vat, remove the exhausted plant, set it to dry for fuel, clean out the vessel, and stratify fresh plants in it. The fermented plant appears still green, but it has lost three-fourths of its bulk in the process, or from 12 to 14 per cent. of its weight, chiefly water and extractive matter.

The liquor in the lower vat must be strongly beaten for an hour and a half, when the indigo begins to agglomerate in flocks, and to precipitate. This is the moment for drawing off the liquor; whether any error has been committed in the fermentation; which must be corrected by the operation of beating. If the fermentation has been arrested too soon, much froth rises in the beating, which must be allayed with a little oil, and then a rich blue appears. If large round granulations are formed, the beating is continued, in order to break them up, and to make the liquor finer. If they become as small as fine sand, and if the water clears up, the beating is allowed quietly to subside. Should the vat have been over fermented, a thick fat looking crust covers the liquor, which does not disappear by the addition of a flask of oil. In such a case the beating must be repeated, and when the granulations become round, and begin to subside, and the liquor clears up, the beating must be discontinued. When the fermentation has been excessive, the froth or crust dissolves itself spontaneously into separate minute particles, that move about the surface of the liquor. On the other hand, a rightly fermented vat is easy to work; the froth, though abundant, vanishing whenever the granulations make their appearance. The colour of the liquor, when drawn out of the steeping into the beating vat, is bright green; but as soon as the agglomeration of the indigo commences, it assumes the colour of Madeira wine; and speedily afterwards, in the course of beating, a small round grain is formed, which falls down and leaves the water transparent, when all the turbidity and froth vanish.

The object of the beating is threefold; first, it tends to decompose a great quantity of carbonaceous matter in the fermented liquor; secondly, to give the newly developed indigo the requisite dose of oxygen by the most extensive exposure of its particles to the atmosphere; thirdly, to agglomerate the indigo in distinct flocks or granulations. In order to hasten the precipitation, lime water is occasionally added to the fermented liquor in the progress of beating; but those who manufacture the superior quality of indigo avoid the use of lime, as it has a tendency to make the indigo hard and red. In the end of the beating vessel a beam is fixed upright, in which three or more holes are perforated a few inches in diameter. These are closed with plugs during the beating, but two or three hours afterwards, as the indigo subsides, the upper plug is withdrawn to run off the supernatant liquor, and then the lower plugs in succession. The state of this liquor affords, on being examined, an indication of the success of both the processes. When the whole liquor has run off, a labourer enters the vat, sweeps all the precipitate into one corner, and empties the thinner part into a spout which leads into a cistern, 20 feet long, 3 feet wide and 3 feet deep. When all this liquor is once collected, it is pumped through a bag

manufactured indigo from the *Veronica tectoria* or *Veronica*. (Vide Transactions of the Society of Arts, vol. xxviii.) This plant, which grows the size of a small tree, is found in the lower regions of the mountainous tract of Rajahmundry, and also on hills in the neighbourhood of Madras and Pondicherry, and grows in a sterile as well as rich soil. The leaves begin to appear in March and April, and at the end of April have attained their full size, when they are ready for gathering. At the end of August they begin to become a yellow rusty colour and soon fall off. The leaves yield no colour, and the plant is several years old, but the best leaves for making indigo are those of the first year's plants. They improve when kept for a day or two, and when they begin to wither, they yield but a small portion of very bad colour, and when quite dry only a dirty brown foam. In this they differ from the leaves of the common Indigo plant, which may be dried before extraction without loss of colour. They also differ from the latter in not yielding their colour in cold water. With cold water only a hard, black, stony substance is obtained, not blue indigo. It is therefore necessary to employ hot water, which extracts the colour very readily. The leaves having been collected, are on the following day thrown into copper scalding vessels, which are then filled with cold water to within 2 or 3 inches of the top. Hard water, and only a large quantity of carbonate of lime is better adapted for the purpose than rain water. The fire is then kindled and maintained rather briskly until the liquor acquires a deep brown colour. The leaves then begin to assume a yellowish colour, the heat of the liquor being about 150 to 160° Fahr. The fire is then removed and the liquor run off into the boiling vat. Here it is agitated from 1 to 30 minutes. It is then mixed with about 1/4 to 1/2 part of lime water, which produces a sandy granulation. After the sand has settled the supernatant liquor is of a clear Madeira wine colour. The quantity of colour obtained, amounts to 1 lb. from 250 lbs. of green leaves; but it varies according to the season and the state of the weather. In August and September, the produce is only one half or two-thirds of what it is in May and June, and even that is diminished if the weather is wet, or the leaves are treated immediately after being gathered. The scalding requires about three hours, and the agitation and precipitation the same time. The indigo is improved by treating it with a little sulphuric acid. The only fault it has is, that it breaks into small pieces, unless it has been dried slowly in the shade produced from the sun.

In the southern provinces of China a species of *Indigofera* is extensively cultivated for the sake of the dye which it affords. In the northern provinces two other plants are employed by the inhabitants for the same purpose. Mr. Forster, the well-known Chinese traveler, to whom we owe the description of these plants and of the process of manufacturing indigo from them, states that one of them is grown in the neighbourhood of Shu-chiao, and he has given it the name of *Indigo sinensis*. The other, which is a species of *Jussiaea*, is largely cultivated in the hilly country near Ningpo, or rather in the valleys among the hills. It seems to be easily cultivated; it grows most luxuriantly, and is no doubt very productive. Having evidently been introduced from a more southern latitude, it is not hardy in the province of Chekiang any more than cotton is about Shu-chiao; but nevertheless it succeeds admirably as a summer crop. It is planted at the end of April or beginning of May, after the spring frosts are over, and it is cleared from the ground in October. During the period it attains a height of a foot or a foot and a half, becomes very bushy, and is densely covered with large green leaves. It is cut before any flowers are formed. The plants are grown, not from seed but from cuttings. These cuttings consist simply of a portion of the stems of the previous year, which after being stripped of their leaves are tied into bundles, each containing upwards of 1000, and kept during the winter in a dry shed or outhouse, where after being firmly packed together they are banked round with dry loam, and covered with straw or litter to keep them from the frost. During the winter months the cuttings remain green and plump, and although no leaves are produced a few roots are generally found to be formed or in the act of forming when the winter has passed and the time for planting has become round. In this state they are taken to the fields and planted. The weather during the planting season is generally showery, as this happens about the change of the monsoon when the air is charged with moisture. A few days of this warm showery weather is sufficient to establish the new crop, which now goes on growing with luxuriance and requires little attention during the summer, indeed not except keeping the land free from weeds. In the country where this dye is manufactured there are numerous pits or tanks on the edges of the fields. They are usually circular in form and have a diameter of about 11 feet and a depth of 2 feet. About 400 pieces* of stems and leaves are thrown into a tank of this size, which is

* A Chinese cattie is equal to 1 lb.

then cut to the stem with clear water. It has kept the plant in perfectly sound condition, and the water has become very turbid from the matter. At the present stage of the process the leaves are removed from the stalk with a small hand-made knife or scissor. When every portion has been removed, the water is employed to give the water a regular and rapid motion with the hands, the motion which is continued for some time. Then the part of the uppermost water is removed by hand to make a series of thin white water, which water has been taken out of the tank for the purpose. This is the white water, and the rest of the water is kept up for a few minutes longer. When the time of day has been reached in this way the water is allowed to come. Four or five more times the same process is repeated, leaving the water with hands, rather than for the purpose. The best of the water is a very strong yellow, while the rest is a pale yellow, changing from a greenish to a dirty yellow, while the first becomes a brownish black. During the process the head workman takes a portion of the liquid out of the tank and brings it rapidly with his hand. Later the operation is continued until the water is judged of by the hue it presents. The best of the water is kept for about half an hour. At the end of this time the whole of the surface of the liquid is covered with a thick coating of froth of the most brilliant yellow, in which the particles of indigo, especially near the surface. At this stage, it being desirable to separate the froth with the liquid below it, it is only necessary to throw a small quantity of cabbage or onion on the surface of the froth. The workman then stirs and beats it gently with the flat brooms for a second or two, and the whole is then drawn up. The liquid, which is now darker in colour, is allowed to repose for some hours, until the floating matter has sunk to the lower stratum, when a second third of the liquid is drawn off and thrown away. The remaining third part is then drawn up, and is kept on a lower level, which is covered over with straw, and then it remains for three or four days. By this time the remaining matter has separated. It is then the water, which is now a dark green, and is drawn up for four or five inches of the bottom in the form of a thick paste, and of a beautiful blue colour. In this state it is packed in barrels and exported to the market for sale.

This part of China. Like the Shan-hai idon, made from *Indigo tinctoria*, it is called "T'ien ching" by the Chinese. — *Geographical and Agricultural Gazetteer*, April 18th, 1851.

The cultivation of indigo in Central America, has fallen off very much of late years. Nicaragua formerly exported annually about 200,000 lbs. of it in the bark. At present the export probably does not exceed 100,000 or 200,000 bales. Under the government of Spain, the state of San Salvador produced from 1,000 to 10,000 bales annually. A piece of ground equal to two acres generally produces from 100 to 150 lbs. at a cost of not far from 30 to 40 dollars.

There is an indigenous biennial plant abounding in many parts of central America, which produces indigo of a very superior quality, but gives less than half the weight which is afforded by the cultivated species. The *Indigofera disperma* is the species employed in cultivation. It attains its highest perfection in the richest soils. It will grow, however, upon almost any soil, and is very little affected by drought or by superabundant rains. In planting it, the ground is perfectly cleared, usually burnt over, and divided with an implement resembling a hoe into little trenches, 2 or 3 inches in depth, and 10 or 14 apart, at the bottom of which the seeds are sown by hand, and lightly covered with earth. A bushel of seed answers for 4 or 5 acres of land. In Nicaragua it is usually planted towards the close of the dry season, in April or May, and attains its perfection for the purpose of manufacture in from two and a half to three months. During this time it requires to be carefully weeded, to prevent any mixture of herbs, which would injure the quality of the indigo. When it becomes covered with a kind of greenish farina, it is in a fit state to be cut. This is done with knives at a little distance above the root, so as to leave some of the branches, called in the West Indies "ratons," for a second growth, which is also in readiness to be cut, in from six to eight weeks after. The crop of the first year is usually small, that of the second is esteemed the best, although that of the third is hardly inferior. It is said that some fields have been gathered for ten consecutive years without being re-sown, the fallen seed obviating the necessity of new plantings.

After the plant is cut, it is bound in little bundles, carried to the vat, and placed in layers in the upper or larger one called the *super* (*madura*). This vat holds from 1000 to 10,000 gallons, according to the requirements of the estate. Boards loaded with weights are then placed upon the plants, and enough water let on to cover the whole, which is now left to steep or ferment. The rapidity of this process depends much upon the state of the weather and the condition of the plant. Sometimes it is accomplished in 6 or 8 hours, but generally requires from 12 to 24. The proper length

of time is determined by the colour of the liquid water; but the great secret is to check the fermentation at the proper point, for upon this, in a great degree, depends the quality of the product. Without describing the plant, the water is now drawn off by evaporation in the lower vat or "water vat," where it is strongly and incessantly beaten in the smaller vats with paddles by hand, in the larger by wheels turned by horse or water power. This is continued until it changes from the green colour, which it at first displays, to a blue, and next the colouring matter, or "blue," shows a disposition to separate. This is sometimes hastened by the infusion of certain herbs. It is then allowed to settle, and the water is carefully drawn off. The pale granules, at which time it resembles a fine soft clay; after which it is put into a vat to drain, and then spread on cloths in the sun to dry. When properly dried, it is carefully sorted according to its quality, and packed in hide cases, 150 lbs. each, called *arras*. The quality has not less than 9 gradations, the best being of the highest price. From 6 to 8 are called *flaves*, and are the best, from 3 to 6 from 1 to 3, the next, *brunes*. The two poorer qualities do not pay expenses. A measure of 100 yards square produces on an average about one ceroon at each cutting. After the plant has passed through the vat, it is required by law that it shall be dried and burnt, because in decomposition it generates by the million an annoying insect called the "indigo fly."

The following account of the manufacture of indigo on the Senegal is taken from Perottet's "Atte de l'Indigotier."

The land destined to the cultivation of the plant ought to be perfectly level and free from undulations, so as to prevent the seed from being washed into the hollows or lower parts by the heavy rains so frequent in the tropics. Soils of a greyish colour abounding in clay are not adapted for the purpose, as they are too compact and cold. Sandy soil of a whitish colour must also be avoided. Light soils, abounding in humus or vegetable remains, and having a colour between grey and dark brown, are to be preferred to all others. The soil should at all events, not be one of retentive moisture. The quantity of indigo obtained from the same quantity of plant may vary, according to the soil, from 4 lbs. to 10 lbs. The soil which varies in a corresponding degree. The extent of ground which is required for the production of indigo in a large scale is great, as the refuse of the plant, after the extraction of the seed, is a manure which is found to be attended with very beneficial results. The ground, if new, must be turned up by means of a plough or hoe, to the depth of at least 10 or 12 inches, three times successively at intervals of 3 weeks before the sowing takes place. The sowing must only be undertaken in fine weather, never during heavy rain. The seed employed should be perfectly ripe, and of a plant not more than one year old. It is to be left in the seed-vats to which it is retained until the time when it is wanted. The latter are then put into a wooden mortar and reduced to fragments, and the seed is separated by winnowing from the dust, debris, &c. with which it is mixed. The sowing is to be effected broad cast and as evenly as possible. It should take place, if possible, just before the approach of rain, which the use of a harrow is not required, as the rain generally has the effect of completely leveling the ground and covering up the seed with soil. The *Indigofera tinctoria*, and its varieties *macrocarpa* and *emarginata*, being a plant with a much branched system, it is not necessary, in sowing it, to take more than from 6 to 7½ kilograms of seed to 1 arpent of ground; but the *Indigofera arborescens*, being more sparingly branched, and therefore taking up less room, requires to be more thickly sown. At about ten or twelve days after sowing, when the young indigo has attained a height of about 81 to 100 million trees, the ground must be carefully weeded, and this operation must be repeated as soon as the weeds have again made their appearance and commenced to interfere with the growth of the crop. When the season is favourable three months are generally sufficient to enable the plants to attain the degree of development necessary for the production of indigo. At the period when inflorescence commences the plant is far richer in colouring matter than at any other. As soon, therefore, as there are any indications of flowering, and when the lower leaves, in the axils of which the flowers appear, begin to acquire a yellowish tint, and when pressed in the hand produce a slight crackling noise, no time must be lost in cutting down the plant. This is effected by means of good knives or sickles, and as near the ground as possible. The stems, after being cut, are tied together into bundles of leaves and carried to the manufactory. Since the colouring principle of the indigo plant is extremely susceptible of change by the action of destructive agencies, it is necessary to use the utmost dispatch in gathering the crop, and to have the manufactory of such a size in proportion to the plantation, that no time may be lost in working up the material as soon as gathered. The plants must on no account be cut when they are moistened either with rain or dew, because in this case they acquire a blackish

tion in consequence of the friction to which they are exposed in passing down, and taking them to the point of entry, thus taking a share of the compressions of the ascending water. Besides this, it has been observed that there is the same amount of rain in the same proportion of pressure, and there very considerably, and sometimes even double its quantity, than in the same or nearly the same rain, the plants yield little or no increase. The independent use of the stem in a great number of pillars, which have been supported, is a question not to destroy for a while time. No one can deny that the plants are not to be known. It has been recommended to pass water down over the ground, but the plants have a natural way of doing so, so to crush the water are without harming the plants, and this plan has been attended with partial success.

[illegible]

[illegible]

extracted by Chevreul. He stated that he was not by any means of the opinion that the green colour of leaves is a different colour. In the first a fermentation is effected, in which the action of the atmosphere is not so far removed as in the second process. The principle rises from a fermentation in the leaves of the indigo plant, but the colour is not permanent. The green colour is a product of a fermentation, which gives to the leaves a greenish tint, and renders it a colour of indigo, by the chemical action of other substances. The action of fermentation passes into a destructive fermentation, but the colour is a consequence of a fermentation of a chemical substance. However the following points have been proved by Chevreul. 1. In the second operation, the colour of the leaves is destroyed by water, which, by combining with the colouring principle, destroys its solubility, and gives it the blue colour. The heating process, at the same time, destroys the carbonic acid which is formed in the first operation, and which by its action produces an obstacle to the combination of the oxygen. The appearance of the colour is produced by the action of oxygen, but if an excess be combined, it counteracts the free combination of the oxygen. The third part of the process, that for its object is the destruction of the four gases, to render the colour permanent, which is effected by fermentation, which gives it more or less hardness, where its appearance varies. It is Chevreul's opinion that vegetable alkali is the agent by which the colouring matter was extracted from the plant, and held in solution until it was destroyed by the action of heat. Roemer has concluded from his experiments, "that the indigo plant contains the base of the colour, which is naturally green; that much carbonic acid is decomposed during its extraction from the leaves; that the carbonic acid is the agent whereby it is probably extracted and kept dissolved; that ammonia is not formed during the process; that the use of the alkali employed is to destroy the attraction between the base and the carbonic acid; and that the vegetable base being thereby set at liberty, combines with some principle present in the atmosphere, forming the indigo, a coloured insoluble body, which is the base of the colouring matter."

Chevreul, who was the first chemist of any consequence to examine the indigo-bearing plants, and their action, inferred from his analysis of the *Indigofera tinctoria* and the *Indigofera tinctoria*, that these plants contain indigo in the white or red state, in the same way in which it is found in the red state, that in the state it is held in solution by the vegetable juice, and that when the solution is removed from the plant, it is converted by the action of the atmosphere into the indigo-blue. Chevreul, from an examination of the *Indigofera tinctoria*, drew the following conclusions:—1. Indigo-blue does not pre-exist in the plant, but is formed during the operation by means of which we believe it to be extracted. 2. There exists in a small number of plants a peculiar principle, different from all the known principles of plants, and which has the property of being convertible into indigo; this principle may be called indigo-principle. 3. This principle differs from indigo in remaining in excess of carbon, of which it loses a portion, in passing into the state of indigo-blue, by the action of a small quantity of oxygen which it takes up. 4. The loss of the portion of carbon must be attributed to its undergoing combustion, and being converted into carbonic acid. 5. It differs in its properties from carbonic acid in being colourless and soluble in water, and by its greater combustibility, which causes it to undergo a violent combustion at the red or white temperature of the atmosphere. 6. Its combustion is enhanced by heat and by combination with a saline, especially lime; it is diminished by the action of alkalies, even carbonic acid. About the year 1820, the *Indigofera tinctoria*, an indigo-bearing plant, had become the subject of a series of investigations by several French chemists, who, with a view to ascertain whether this plant, if grown in France, could be advantageously employed in the preparation of a dyeing material as a substitute for foreign indigo. Berthollet and Pelletier, after an examination of this plant, arrived at the conclusion that indigo is contained in it as reduced indigo, in the same state as it is in wool, according to Chevreul. Robiquet, Colin, Turpin, and Joly, on the other hand, expressed a very decided conviction that indigo-blue pre-exists in the plant, but that in a free state, that it is combined with some organic substance or substances, which render it insoluble in water, ether and alcohol; and that the operation of point extraction is required in order to destroy this combination and set the indigo at liberty. The explanation of Chevreul, proceeding from an authority of such eminence, and being the subject, has been adopted by most chemists. Nevertheless there are objections to it which render it inadmissible. Reduced indigo is a body which is only soluble in alkalis, and cannot, therefore, be contained as such in the juice of indigo plants, which is mostly acid. As it also takes up oxygen with the greatest avidity, and is converted into indigo-blue, it is difficult to conceive how the whole of it can be preserved in a colourless state in the cells of plants, in which it must continually come in contact

with the oxygen element by the vegetable system. If these plants contained red matter, the juice would, however, turn blue the moment it became exposed to the atmosphere, which is not always the case. The necessity for a long process of fermentation in order to obtain the coloring matter would then not be very apparent, for there would be no need of any fermentation, it being all that was necessary for the purpose. The difficulty with which the process is destroyed if the process of fermentation is carried too far, is in accordance with the supposition that it is vegetable in its origin, and is a decomposed substance, since indigo-blue is a body not easily decomposed except by very powerful agents.

In order to throw some light on this subject, an investigation was undertaken by Schrank into the nature of the indigo-blue which exists in the *Indigo tinctoria*, or common indigo plant, which is the only plant of this kind in Europe that yields any considerable quantity of the coloring matter. Schrank succeeded in obtaining from that plant a substance of very peculiar properties, to which he gave the name of *Indican*. It is a substance which has the appearance of a yellow or light brown transparent syrup. It has a bitter taste. It is very easily soluble in water, alcohol, and ether; its solutions are yellow and have an acid reaction. Its compounds with bases are yellow. When its watery solution is mixed with a strong acid, such as a muriatic or sulphuric acid, no color takes place at first, but on leaving the solution to stand, or on heating it, it becomes blue and precipitates, then turns to a purple color, and at length deposits a quantity of purple indigo-blue, which is quite insoluble in water. These floccs remain for the most part of indigo-blue, but they contain also a red coloring matter and a small amount of a resinous substance. The supernatant liquid contains a peculiar kind of sugar, and on being distilled, yields carbonic, formic, and acetic acids. It thus appears that the plant does not contain indigo-blue ready formed either in the blue or colorless state, that the latter exists in the vegetable juice in a state of combination with sugar, forming a compound of that peculiar class known to chemists as *glycosides*. This compound is readily dissolved by water, and the indigo-blue may then be liberated and precipitated from the solution by means of acids, and probably a long series of agents, but the simultaneous action of oxygen is not necessary during the process of decomposition, which the compound undergoes in yielding indigo-blue. Now if, as is very probable, the various species of indigo-fer contain indigo-blue in similar substance, the phenomena which take place during the process of fermentation of indigo may easily be explained. During the steeping process the indigo is dissolved, and in consequence of the fermentation which then takes place in the liquor it is decomposed into indigo-blue and sugar. The former would then be precipitated, but a new ammonia is, according to most authors, evolved at the same time; the indigo-blue is, by the simultaneous action of the alkali and the sugar, or other fermentative matter contained in the liquid, reduced and dissolved, forming a true indigo-vat, from which the coloring matter is afterwards precipitated by the combined action of the atmospheric oxygen and the lime, during the heating process. According to Schrank, the distillation which may be observed in the decomposition of indican during the first period, indigo-blue is the chief product of decomposition; during this period, the red and brown resinous matters make their appearance with very little indigo-blue. The formation of carbonic, acetic, and formic acids is, according to Schrank, dependent on that of the brown resinous matters. It would appear, therefore, that the copious discharge of carbonic acid, as well as the acid taste, attributed to acetic acid, sometimes observed during the manufacture of indigo, are phenomena which indicate the formation, not of indigo-blue, but of other substances, which may prove very injurious to the quality of the indigo. These substances being soluble in alkali, but insoluble in water, are precipitated, as soon as the liquid loses the alkaline reaction which it possesses at the commencement, and becomes acid. Though indigo-blue is a body of very stable character, not easily decomposed when once formed, except by potent agencies, and the assertion of Perrotet and others, that "nothing is more fugitive and more liable to be acted on by destructive agencies, than the coloring principle of the indigo-fer," will be easily understood when the following facts, mentioned by Schrank, are taken into consideration. If a watery solution of indican, the indigo-producing body, be boiled for some time, it then yields by decomposition, not a trace of indigo-blue, but only indigo red, and if it be boiled with the addition of alkalis, it then gives neither indigo-blue nor indigo-red, but only the brown resinous matters before mentioned. The mere action of alkalis is therefore sufficient to cause the molecules, which would otherwise have gone to form indigo-blue, to arrange themselves in a totally different manner and yield products which bear very little resemblance to it. It is evident, therefore, that one of the chief objects to be kept in view by the manufacturer of indigo, is the proper regulation of the process of fermentation, so as to prevent the formation of the other products, which take the place of indigo-blue, and are formed at its expense.

dried. The plants are either round, or fluted, and square, or of irregular shape. The quality is very unequal. Java produces the flatter, square, or less elongated masses, the quantity approaching that of Brazil. Both these kinds are consumed chiefly on the continent of Europe.

Guatemala indigo is exported from the country in skins or hide wrappers, each containing about 1 lb. of the root. It is said to be made irregular pieces, which are more or less brittle, compact, lighter than water, and of a bright blue colour with an occasional tinge of white. There are three kinds of the Guatemala indigo, viz. 1. *Barva*, which is the best, and superior in quality, that of the finer Brazilian indigoes; 2. *Atlixco*, and 3. *Copala*, which is the lowest in quality, being heavy, difficult to break, and of a dingy red colour. Of the first kind very little now reaches the market. The indigo of Caraca is, generally speaking, inferior to that of Guatemala.

The manufacture of indigo was formerly carried on in St. Domingo, but has for some time been entirely abandoned.

The indigo of commerce, even when not adulterated, is a mixture of different matters. When it is heated in a state of fine powder to 212° F. it loses from 5 to 10 per cent. in weight, the loss consisting of water. When the dry powder is heated in a crucible, a great part of it burns away, and there is left at last a greyish ash, consisting of the carbonates and phosphates of lime and magnesia, silicate of lime, alumina, oxide of iron, clay, and sand. These matters are partly derived from the plant, partly from the lime and the impurities of the water employed in the manufacture. The quantity of impurities retained in ordinary indigo varies very much. In the finer quality it amounts on an average to about 10 per cent. of the weight, whilst in the inferior quality commonly of Mexican indigo, it rises to between 30 and 40 per cent. The organic portion of the indigo, or that which is dissipated when indigo is heated, also consists of several different substances.

By treating indigo with various solvents, Berzelius obtained, besides indigo-blue, the true colouring matter of indigo, three other bodies, viz. *indigo-gluten*, *indigo-brown*, and *indigo-red*, which seem to be contained in various proportions in all kinds of indigo. Indigo-gluten is obtained by treating indigo with dilute sulphuric, muriatic, or acetic acid, and then with boiling water. It is left on evaporation of its solutions as a yellow transparent extract, which is soluble in spirits of wine, and easily soluble in water, more diffusible in cold liquids. Its taste is like that of extract of meat. It yields by dry distillation much ammonia and a fixed oil, and behaves in most respects like vegetable gluten. On treating the indigo, after being freed from the indigo-gluten, with hot strong caustic lye, the indigo-brown is either with a little indigo-blue dissolved, forming a dark brown, almost black solution, from which the indigo-brown after filtration from the portion insoluble in alkali is precipitated by means of acid. After being purified, indigo-brown has the appearance of a dark brown transparent resin, which is almost tasteless and quite neutral. By dry distillation it affords ammonia and capricumatic oil. It is decomposed by nitric acid and chlorine. It combines both with acids and bases. Its compounds with alkalis are dark brown, and easily soluble in water. The compound with baryta is not easily soluble in water, and that with lime is insoluble. By boiling the alkaline compounds with lime in excess the indigo-brown may be separated and rendered insoluble. The green substance obtained by Clavier from indigo seems to have been a compound of indigo-brown with ammonia containing a little indigo-blue, either in a state of combination or mechanically intermingled. Indigo-brown seems to bear a great resemblance in many of its properties to the brown resinous substances obtained by Schunck in the decomposition of indican with acids. From its constant occurrence in all kinds of indigo, it may be inferred that it is not a mere accidental impurity, but stands in some unknown relation to indigo-blue. As long, however, as its origin and composition are unknown, this must remain a mere supposition. After the removal of the indigo-gluten and indigo-brown, the indigo is extracted with boiling alcohol of specific gravity 0.83. A dark red solution is obtained, which is filtered and distilled, when the indigo-red contained in it is deposited as a blackish brown powder, which is quite insoluble both in water and in alkaline liquids. Indigo-red, according to Berzelius, is amorphous, but by distillation in vacuo yields a white crystalline substance, as well as unchanged indigo-red. Concentrated sulphuric acid dissolves it, forming a dark yellow solution, which deposits nothing on being mixed with water; the diluted solution is rendered colourless by wool, which at the same time acquires a dirty yellowish-brown or red colour. The description given by Berzelius leaves it doubtful whether the indigo-red obtained by him from indigo was a pure unmixed substance. From the leaves of the indigofern, as well as from those of the *Jussiaea bartramia*, a substance may, according to Schunck, be extracted which has received from him the name of *indurbin*, but which seems to be merely indigo-red in a state of purity. This substance has, according to Schunck, the following properties: it crystallizes in small silky needles of a brownish-purple colour, which when rubbed

with a hard body show a bright coppery blue. When carefully heated it gives to strongly reddish, and on a very slow fire, or in the form of long plates, a smoky brown, leaving a black carbonaceous residue. It dissolves in concentrated sulphuric acid, forming a solution of a beautiful purple colour, which when diluted with water yields a deposit and then imparts a fine purple colour to cotton, wool, and silk. It is insoluble in water, but dissolves in boiling alcohol with a suspended purple colour. It is insoluble in a strong solution of water exposed to the gradual action of a salt and boiling spirits, just as it is insoluble when forming a solution from which it is again precipitated on exposure to the vapour of the atmosphere. This solution does not turn purple. In some of its properties this body bears a striking resemblance to indigo, and the comparison of the two is almost exact.

It has been doubted whether these various solutions or impurities with which indigo is associated produce any effect in the dyeing process or colour. In a number by Schwarzenberg, to which a prize was awarded by the French Institute in 1810, the author arrives at the conclusion that neither indigo, nor any of its impurities, nor any of the various preparations which are used to treat it, are prepared with pure indigo. Nevertheless differences are observed in dyeing with different kinds of indigo, which he has only to explain in the supposition that water, though being indigo, takes part in the process. In the ordinary blue vat, made with sulphate and lime, any effect which might be produced by indigo, by the yellow-brown is destroyed by the lime, which forms with it an insoluble compound. Indigo, however, dissolves, as we would expect, in alcohol with a blue and red-violet colour, and the alcohol imparts a purple colour to water. In the red vat indigo and its impurities may be detected by precipitating a portion of the liquor, and treating the precipitate with boiling alcohol, which then usually imparts a red colour. It is possible, therefore, that a small part of the indigo produced is dyes with indigo, and is due to indigo-red.

The portion of the indigo which remains after treatment with spirit, alkali, and alcohol remains essentially of the same blue, the true coloring matter of indigo, which, however, with each earthly particle, and other impurities. In order to purify it, the residue, which still remains, is to be mixed with lime, the quantity of which must amount to twice the weight of the crude indigo, and which has been previously dried with water. The mixture is then put into a bottle capable of holding about 150 times its volume of water, and the bottle is filled up with boiling water and shaken. A quantity of finely powdered proto-phosphate of iron, amounting to 1/2 of the weight of the lime is then added, the bottle is closed with a stopper, well shaken, and left to stand for several hours in a warm place. The mass gradually becomes green, and the indigo-blue is then converted by the precipitated proto-phosphate into red indigo, which dissolves in the excess of lime, forming a deep yellow solution. This solution when clear is poured off from the deposit into a vessel containing a sufficient quantity of dilute nitric acid to supersaturate the whole of the lime. The red indigo which is precipitated in greyish-white flocks, is agitated with water until it has become blue, and the regenerated indigo-blue is collected on a filter and washed with water, in order to remove the chloride of calcium and excess of nitric acid. The following method of obtaining pure indigo-blue has been recommended by Priestley: 4 oz. of crude indigo and the same weight of grape sugar are put into a bottle capable of holding 12 lbs. of water; a solution of 6 oz. of concentrated caustic soda in 1 lb. of alcohol is then added, after which the bottle is filled with hot spirits of wine of 75 per cent., and the whole is fitted up for the time. The liquid becomes at first white, then yellow, and on being filtered and left exposed to the air, deposits the indigo-blue in small crystalline scales, which are to be filtered off and washed at first with alcohol, and then with water.

Pure indigo-blue has the following properties:—Its colour is dark blue inclining to purple. When rubbed with a hard body it assumes a bright coppery brown. It has neither taste nor smell, possesses neither acid nor basic properties, and belongs, as regards its chemical affinities, to the class of indifferent substances. Its specific gravity is 1.50. When heated in the open air it melts, boils, and burns with a smoky flame, leaving a carbonaceous residue. But when it is heated in a vessel partially closed, or in vacuo, it begins to evolve at a temperature of about 550° F. a violet-colored vapour, which condenses on the colder parts of the apparatus in the form of long crystalline needles, which are blue by transmitted light, but exhibit by reflection light a beautiful coppery lustre. These needles are insoluble in alcohol. A great portion of the indigo-blue is however decomposed during the heating process. Indigo-blue is insoluble in water, alcohol, and dilute acids. Boiling alcohol and boiling oil of turpentine dissolve a minute quantity of it, and deposit it when on cooling. Fixed oils also dissolve a little of it at a heat exceeding that of boiling water, yielding blue solutions, the colour of which, when the heat is further increased, changes, becoming

to Mr. Cruik, first to crystallise and then to distil. By the action of dilute nitric acid on indigo, a blue crystalline acid is converted into isatin, a body soluble in water and crystallising to red needles. Colourless indigo-purplish, dissolving it in concentrated sulphuric acid, a substance having properties very similar to those of isatin. Both isatin and the indigo-purplish, when dissolved with different reagents a great number of products are formed, some of which have, however, as yet found any application in the arts. By the action of concentrated sulphuric acid indigo-blue is converted first into indigo-sulphuric acid, a white crystalline acid, and then into antipicric acid, which is yellow and crystalline. The latter is sometimes employed for imparting a yellow colour to silk and wool, but it is generally prepared from cheaper materials than isatin. The action of concentrated sulphuric acid on indigo-blue is very remarkable. When the acid is poured on the pure substance and gently heated it becomes in the first instance a green colour, which changes after some time to blue. No gas of any kind is evolved. When however crude indigo is employed, there is a perceptible disengagement of sulphurous acid, resulting from the action of the sulphuric acid on the impurities of the indigo, such as the indigo-gluten, &c. (1) adding water, a solution of a beautiful deep blue colour is obtained. The filtered liquid contains a peculiar acid, to which the names of *indigo-sulphuric*, *sulphurindigo*, *indigo-sulphuric*, or *carbazone-sulphuric acid* have been applied.

This acid is a so-called double acid. It contains indigo-blue and sulphuric acid, but in such a peculiar state of combination, that neither of the two constituents can be detected by ordinary reagents, nor again eliminated as such from the compound. It combines with bases without either of the two constituents separating. The compounds are called *indigo-sulphates*, and are, like the acid, of a dark blue colour. When the solution of indigo-blue in concentrated sulphuric acid is diluted with water, there is usually formed a small quantity of a dark blue flocculent precipitate, which is the phenomenon of Mr. Cruik, or the *indigo-purple of Herapain*. It is a compound of indigo-blue with sulphuric acid, containing less of the latter than indigo-sulphuric acid. It is always formed when the quantity of sulphuric acid employed is not more than eight times that of the indigo-blue, or when the action of the acid on the latter has continued for only a short time. By heating it with an excess of acid it is changed into indigo-sulphuric acid. Though soluble in concentrated sulphuric acid, it is insoluble in the dilute acid, and hence is precipitated on the addition of water. On filtering and washing, however, it begins to dissolve, as soon as the free sulphuric acid has been removed, and may then be completely dissolved by pure water. The solution has a blue colour, just like that of indigo-sulphuric acid. Its compounds with bases have a blue colour with a purplish tinge. The blue acid liquid filtered from the indigo-purple on being supersaturated with carbonate of potash or soda, deposits a dark blue powder, which consists of the indigo-sulphate of potash or soda. These compounds are too little in water containing a large quantity of neutral salts, and are therefore precipitated when the excess of sulphuric acid is neutralised by carbonate of potash or soda. As soon, however, as the sulphate of potash or soda has been removed by washing, the indigo-sulphate may be dissolved in pure water, yielding a dark-blue solution. The indigo-sulphates of the alkalis may also be prepared by steeping wool, previously well cleaned, in the solution in sulphuric acid. The wool takes up the colour, becoming of a dark blue colour, and after having been well washed with water, in order to remove the excess of acid as well as the impurities which are always present in the solution when crude indigo has been employed, is treated with carbonate of potash, soda, or ammonia, which separate the acid from the wool, and produce blue solutions containing the salts of the respective bases. The indigo-sulphates of the earths and metallic oxides, which are mostly insoluble blue powders, may be obtained from the alkaline salts by double decomposition. By an excess of caustic alkali, indigo-sulphuric acid is immediately decomposed, giving a yellow solution, from which it is impossible to obtain the acid again. By means of reducing agents, such as sulphuretted hydrogen, nascent hydrogen, proto-salts of tin and iron, &c., indigo-sulphuric acid is decolourised, but the colour is restored by the oxygen of the atmosphere. Indigo-sulphuric acid, in a free state or in combination with alkalis, is employed in the arts for the purpose of imparting a blue colour to silk and wool. It has very little affinity for cotton fibre, but is nevertheless employed occasionally for bluing white cotton-yarn and other bleached goods.

By treatment with strong boiling caustic potash or soda lye, indigo-blue is gradually decomposed and converted into a colourless crystalline acid, *anthranic acid*. By weak solutions of caustic alkalis, it is not in the least affected. If, however, it be subjected to the combined action of an alkali or alkaline earth and some body having a strong affinity for oxygen, such as protoxide of iron or tin, sulphur, sulphurous or phosphorous acid, or organic matters, such as grape-sugar, &c., it disappears by degrees, yielding a yellow solution, containing in the place of indigo-

the mother substance which has been called indigotin, indigo, or indigo-blue. While the extract of indigo is added to the water, the indigo-blue is precipitated as a white or greyish white body, which on drying and exposure to the atmosphere rapidly becomes blue, and on immersion into indigo-blue is dissolved in water, but slightly soluble in alcohol. It is soluble in ether, stramonium, lime, and lime-water. The extract of indigo-blue is mixed with a portion of red iron oxide, and the mixture is used for the purpose of coloring. Its composition is not known, and the value which are obtained in water, may be obtained by the method of precipitation. Thus, if a quantity of copper, when added to the mixture, is added, it is dissolved by the action of the water, the value of indigo being reduced to indigotin. Indigotin is also converted into indigo-white, when it is exposed to the action of ammonia or potassium hydroxide, in the presence of water. If the decomposition of indigo is the reduction of indigo and ammonia, which is usually found in the presence of pure indigo, in the absence of the indigo. If a portion of indigo, which is added to the mixture, is added to the mixture of indigo-white and ammonia, the mixture is converted into a blue color, which may be made deeper by repeated additions and subsequent exposure. It is the presence of indigo-white that the mixture is converted into indigo-blue.

The true chemical formula of indigo-blue, which was first determined by M. Chevreul, is $C_{16}H_{10}N_2O_2$, and it is a substance which by addition of water, is converted into a blue color, and it is a substance which is soluble in water. The formula of indigo-blue is $C_{16}H_{10}N_2O_2$, and it is a substance which is soluble in water. Indigo-blue, which is taken up during the so-called reduction of the latter, and then again by oxidation during its conversion into indigo-blue.

Since the value of indigo-blue is entirely in the quantity of indigo-blue which it contains, it is of great importance to ascertain the exact amount of the latter in any given sample of the article. Before commencing the determination of the indigo-blue, a weighed portion of the indigo-blue is heated for some hours at $210^{\circ} F.$, and then weighed again. The loss in weight which takes place represents the amount of water contained in the sample. A weighed quantity of the dried indigo-blue is then to be heated over the flame of a lamp until all the organic matter has been burnt away. By weighing the residue which is left the amount of ash or inorganic matter is ascertained. In order, in the next place, to determine the amount of indigo-blue, several methods have been devised by various chemists, some of which, however, yield very accurate results. Of these methods the following are the principal ones.

1. A weighed quantity of finely powdered indigo is mixed with water in a porcelain mortar. An equal weight of pure lime is then added with water and the mixture is well mixed with the indigo. The mixture is then poured into a stoppered bottle of known capacity, and the mortar is well rinsed with water, which is added to the bottle. The bottle is now heated in a water-bath for several hours, and a quantity of finely powdered sulphate of iron is added; the bottle is then filled up with water, the stopper is inserted, and after the contents have been well shaken the whole is allowed to rest for some hours, until the indigo has become reduced and the sediment has sunk to the bottom. A portion of the clear liquor is then drawn off with a siphon, and the quantity of liquid having been accurately measured, it is mixed with an excess of muriatic acid, and the precipitate, after having been collected, is collected on a weighed filter and well washed with water. Lastly, the filter with the precipitate is dried at $210^{\circ} F.$ and weighed, and the weight of the filter having been subtracted from that of the whole, the weight of the indigo-blue is ascertained. Supposing now that the whole quantity of liquid had been 200 measures, that 40 measures had been drawn off yielding 10 grains of indigo-blue, then the sample contained 100 grains of the latter. For 60 grains of indigo it is necessary to take from the 210a of water.

According to Mr. John Dale of Manchester, who has had great experience in the valuation of indigo for practical purposes, this method, though rather long and tedious, still gives more accurate results than any other. The quantity of indigo-blue indicated by it is generally below the actual quantity contained in the sample. According to Berzelius this loss arises from the lime forming an insoluble compound with a portion of the reduced indigo-blue. Mr. Dale, however, is of opinion, that even when every precaution has been taken, a certain loss, proceeding from some hitherto unascertained cause, cannot be avoided. When for instance pure indigo-blue is treated with lime and copperas in the manner just described, the quantity which is again obtained by precipitation from any portion of the liquid is always less than what it should be by calculation, even when no excess of lime has been employed.

2. The second method of determining the indigo-blue is performed as follows. About 15 or 20 grains of pure indigo-blue, obtained by precipitation from the indigo vat, and the same quantity of the indigo to be tested, which must be previously ground

to a fine powder, are weighed off, and each of them is treated with about 12 times its weight of concentrated sulphuric acid in a flask or porcelain basin. After being heated at a temperature of 150° to 175° F. for about 4 hours, and occasionally well agitated, the two liquids are mixed with water, so that the volume of the two shall be exactly equal. Two equal measures of a weak solution of hypochlorite of lime are then taken, and to the first is added a quantity of the solution of pure indigo. The colour is observed by the colour of sulphuric acid in the solution destined to the blue colour of the concentrated acid. More of the solution must be added until the liquid becomes a greenish tinge, and the number of measures necessary for the purpose is noted. The same experiment is then made with the solution of crude indigo. The quantity of indigo-blue in the latter is of course in inverse ratio to the number of measures which are requisite in order to take up the weight of the solution which is taken. If, for example, the same quantity of hypochlorite of lime dissolves 17 measures of the solution of pure indigo, and 24 measures of the solution of crude indigo, then the quantity of indigo-blue is $17 : 24 :: 100 : x$, and $x = 81.4$.

A number of samples of indigo may be tested in this manner at the same time. Care must be taken to prepare a fresh solution of hypochlorite for every series of trials, and this solution undergoes a certain standard, e.g. which is inapplicable as a standard of comparison. It is necessary also to pay great attention at the moment when the greenish colour indicating an excess of the solution of indigo begins to appear, for it will soon be found that this colour disappears after standing a few minutes, and a fresh quantity of the blue solution must then be added cautiously, until the greenish tinge becomes permanent, even after standing for some time. Modifications of this process have been introduced by various chemists by the use of permanganate of potash, chlorate of potash, or chromate of potash, in the place of hypochlorite of lime; but as the principle in which this process depends is in each case identical and the modulus operandi is almost the same, it will be unnecessary to enter into any minute description of these modifications. The whole method is, however, open to serious objections, and the results which it affords cannot at all be depended on. In the first place, it is difficult to institute a strict comparison between the different shades of colour resulting from the decomposition of the sulphate of indigo in different cases, since the purplish-green tinge observed when an excess of the pure sulphate has been added to the decomposing acid, gives place to a dirty olive or brownish-green, when a solution of crude indigo is employed, in consequence of the impurities contained in the latter. Secondly, it is almost impossible to avoid the formation of a certain quantity of sulphurous acid during the action of concentrated sulphuric acid on crude indigo. This sulphurous acid, during the following operation, becomes oxidized before the blue sulphate is destroyed, and hence the percentage of indigo-blue is apparently raised. In applying this method, it is common to find more than 80 per cent. of indigo-blue in a good sample of indigo, whereas the best qualities seldom contain above 60 per cent., and average quantities between 40 and 50 per cent. This method may show a percentage of 70 indigo-blue, when the method first described indicates between 30 and 60.

3. The third method of estimating the indigo-blue is performed in the following manner. Equal weights of the samples to be tested are treated with equal quantities of concentrated sulphuric acid in the manner above described, and the solutions are then diluted with water and introduced into graduated glass cylinders, water being added to each until they all exhibit exactly the same shade of colour. The richer the sample is in indigo-blue, the greater will be the quantity of water necessary for this purpose, the number of measures of water required in each case indicating the relative amount. The great objection to this method consists in the circumstance, that the different kinds of indigo do not give the same shade of blue when their solutions in sulphuric acid are diluted with water, some exhibiting a pure blue colour, others a blue with a greenish, or purplish tinge. It therefore becomes difficult to institute an exact comparison between them.

Preparation of indigo in dyeing.—As indigo-blue is insoluble in water, and as it can penetrate the fibres of wool, cotton, silk, and flax only when in a state of solution, the dyer must study to bring it into this condition in the most complete and economical manner. This is effected either by exposing it to the concurrent action of alkalis and of bodies which have an affinity for oxygen superior to its own, such as certain metals and metallic oxides, or by mixing it with fermenting matters, or finally, by dissolving it in a strong acid, such as the sulphuric. The first method is that which is employed in the

Copperas or common blue vat.—Before being used the indigo must be broken into small pieces, the size of nuts, moistened with hot water, and then left for a day; after

which it is reduced to a soft paste in a mill. The indigo mill is represented in the annexed cut.

It is a four-sided stone wheel, $\frac{3}{4}$ of 11 in. in diameter, 18 inches broad, and 12 inches deep, cylindrical or rounded in the last part, and revolving upon gudgeons in a wooden frame. It has an iron bar h , consisting of two levers, between which the mill is set so as to revolve on a vibratory motion from the crank d . In the construction, a frame e , which is connected to the centre by two pieces $e' e'$, is caused to vibrate and

the part allowing movement to six iron rollers f, f, f , four inches in diameter, three being on each side of the frame, which triturate the indigo mixed with water into a fine paste. This mill is capable of grinding 1 cwt. of indigo at a time. Whenever the paste is uniformly ground, it is drawn off by the screw g , which had been previously fixed up by a screw plug, in order to prevent any of the indigo from lodging in the crevice of the crank, and thereby escaping the action of the rollers.

Mills of other forms are also used commonly. One of these consists of a horizontal iron wheel, open at the top, in which a stone of corresponding shape is fixed, so as to leave a small space between it and the sides and bottom of the vessel, in which the indigo and water are necessary triturated with water, the motion being produced by means of a vertical shaft fixed to the centre of the stone.

The other ingredients necessary for setting the vat are sulphates or pyrites of iron, newly washed, quinine, and water. Various proportions of these ingredients are employed, as for instance, 1 part by weight of indigo (dry), 4 parts of copperas, and 1 of lime; or 1 of indigo, 2 of copperas, and 3 of lime; or 1 of indigo, 14 of copperas, and 20 of lime; or 1 of indigo, $\frac{1}{2}$ of copperas, and 1 of lime. The sulphate of iron should be as free as possible from the red oxide of iron, as well as from sulphate of copper, which would re-oxidise the reduced indigo-blue. The vat having been filled with water to near the top, the materials are introduced, and the whole after being well stirred several times is left to stand for about twelve hours. The chemical action which takes place is very simple. The protoxide of iron which is set at liberty by the lime reduces the indigo-blue, and the indigo-white is then dissolved by the excess of lime, forming a solution, which, on being examined in a glass, appears perfectly transparent and of a pure yellow colour, and becomes covered whenever it comes into contact with the air, with a copper-coloured pellicle of regenerated indigo-blue. The sediment at the bottom of the vat consists of sulphate of lime, peroxide of iron, and the insoluble impurities of the indigo, such as indigo-brown, iron, &c., with lime, as well as sand, clay, &c. If an excess of lime is present, a little reduced indigo-blue will also be found in the sediment in combination with lime.

The copperas vat is employed in dyeing cotton, linen, and silk. The cotton goods no other kind of vat is used at the present day. The dyeing process itself is very simple. The vat having been allowed to settle, the goods are plunged into the clear liquor, and after being gently moved about in it for some time are taken out, allowed to drain, and exposed to the action of the atmosphere. Whilst in the liquid the fabric attracts a portion of the reduced indigo-blue. On now removing it from the liquid it appears green, but soon becomes blue on exposure to the air in consequence of the oxidation of the reduced indigo-blue. On again plunging it into the vat, the de-oxidising action of the latter does not again remove the indigo-blue which has been deposited within and around the vegetable or animal fibre, but on the contrary, a fresh portion of reduced indigo-blue is attracted, which on removal from the liquid is again oxidised like the first, and the colour thus becomes a shade darker. By repeating this process several times, the required depth of colour is attained. This effect cannot in any case be produced by one immersion in the vat, however strong it may be. The beauty of the colour is increased by finally passing the goods through

ulated sulphuric or nitric acid, which removes the adhering lime and oxide of iron. After being used for some time the vat should be reconstituted or fed with more acid and lime, upon which depends the colour which is first obtained, and then allowed to settle again, so as to leave the liquor clear. The liquor, however, is in course of time gradually renewed, and by degrees the vat becomes capable of dyeing all shades of blue. When the colour produced by it is only very faint, it is no longer worth while using it, and the contents are then thrown away. In dyeing cotton with indigo, it seems to be essential that the red and yellow blue should be in combination with lime. If pounds of soda be used in its stead it is impossible to obtain dark shades of blue.

When cotton piece goods are to be dyed of a uniform blue, they are not submitted to any preparatory process of bleaching or washing. Indeed the size contained in native cotton goods seems rather to facilitate than to impede the dyeing process. In dyeing these goods a peculiar roller apparatus is employed. When certain portions of the fabric are to retain their white colour a different plan is adopted. The pieces having been bleached, those portions which are to remain white are printed with an indigo resist. These resist marks consist generally of some salt of copper, mixed with an appropriate thickening material. The copper salt acts by retaining the vegetable matter at the surface, and thus preventing it from entering the interior of the vegetable fibre; it is only when deposited within the fibre itself that the colouring matter becomes permanently fixed. The pieces are now stretched upon square drying frames, made of wood or of iron, furnished with sharp hooks or points of attachment. These frames are supported by cords over a pulley, and the pieces are immersed and lifted out alternately at proper intervals. In dyeing, a set of 10 vats is used, the first vat containing 1 or 2 lbs. of indigo, and the quantity increasing gradually up to 10 lbs. in the last vat. The pieces are dipped for 7½ minutes in the first vat, then taken out and exposed to the air for the same length of time, then dipped in the second vat, and so on to the last. After passing through the last vat, a small bit of the calico is dried, in order to see whether the colour is sufficiently dark. If it is not, the whole series must be dipped once more in the same vat in which the last dipping was performed. When the bottom of the vat is raked up, as to have more lime in suspension, the vat becomes what the dyer calls *hard*, that is to say, the oxide of copper of the resist is precipitated in a compact state, and consequently acts with more efficiency. But when the vat has been at rest for some time, and there is little lime in suspension, then it is called *soft*. When it is in this state, the oxide of copper is thrown down in a bulky form, and when the pieces are afterwards agitated in the liquor, in order to detach the scale of iron, which always floats about in the vat, and attaches itself to the fabric, and which if left adhering would cause light stains, technically called *grounding*; then the oxide of copper is also detached, and the indigo penetrates to those parts which are to remain white. When cotton yarn is dyed in the copperas vat, the latter is generally heated by means of steam pipes passing through the liquor, the colour being given to the colour the particular place or figure, which is required in this class of goods. No preparatory process is required, except simply stretching in hot water. In dyeing, wooden pins are put through the hanks, the ends being in supports passing over the top of the vat, and the yarn is then slowly turned over, one half being in the liquor, the other half over the pins. It is then taken out, wrung, exposed to the air, and again dipped, this operation being repeated until the requisite shade is obtained.

The methods employed for producing the colours called *China blue* and *pearl blue* on calico have been described under Calico Printing.

The *urine vat* is prepared by digestion of the ground indigo in warmed stable urine, which first decoctifies the indigo-blue, and then dissolves it by means of its ammonia. Madder and alum are likewise added, the latter being of use to moderate the fermentation. This vat was employed more commonly formerly than at present, for the purpose of dyeing woollen and linen goods.

Wood vat.—In former times, wood was the only material known to the dyers of Europe for producing the blue colour of indigo. For this purpose it was previously submitted to a peculiar process of fermentation, and the product was named *pastel* in France. For most purposes indigo has taken the place of wood in the dye-house, and for cotton goods it is now used alone. In the dyeing of woollen goods, however, the use of wood has been retained to the present day, for the purpose rather of exciting fermentation and thus reducing the indigo which is employed at the same time, than of imparting any colour to the material to be dyed. Indeed, the wood used by woollen dyers in this country contains no trace of colouring matter. Various substitutes, such as rhubarb leaves, turnip tops, wild, and other vegetable matters, have accordingly been tried, but without success, since the fermentation is more steadily maintained by means of wood than by any other material. *Pastel*, which

Lewis, who made exact experiments on India, obtained the preparation of three parts of glue in one of sulphate of iron which, with a strong gum, will answer very well; the good parts will admit of very easy use.

Red ink.—This ink may be made by adding for three or four days a weak vinegar, Brazil wood chipped into small pieces, the infusion may then be poured upon the wood for an hour, removed and the strong solution will give Arabic and sugar. A little alum improves the colour. A decoction of gamboge with a little water of ammonia, forms a more beautiful red ink, but it is fugitive. An extremely poisonous red ink of the same kind may be made by dissolving arsenic in weak water of ammonia, and adding a little gamboge.

Blue ink.—Mr. Berthollet's patent blue ink is made by dissolving Prussian blue in a solution of gum arabic. The blue powder is washed in dilute nitrous acid. M. Herberger has given the following as the best formula for blue ink:—

Mix 4 parts of gamboge with 10 parts of water, add 2 parts of water, then add 4 parts of cyanide of potassium dissolved in a little water, collect the precipitate formed, wash it with several additions of water, allow it to drain and it will be about two parts; add to this one part of gum arabic, and a generous quantity of the cyanide by shaking the bottle containing the mixture. The solution of gum arabic must be aqueous, and very agreeable, covering a proportion of about one-fifth of the ink. It may be kept without any addition for a long time.

Chinese Indelible Ink.—I have seen, that lamp black purified by potash lye, when mixed with a solution of glue and dried, formed an ink which was preferred by artists to that of China. M. Muriere, in his interesting treatise entitled *De la Peinture et l'Encre*, says, that the Chinese do not use glue in the fabrication of their ink, but that they add vegetable juices, which render it more brilliant and more indelible upon paper. When the best lamp black is levigated with the purest solution or solution of glue, it forms no doubt an ink of a good colour, but when the strong fracture, and is not so permanent on paper as good Chinese ink, and it is also not so weather into a tremendous jelly. One may be deprived of the disadvantage property by leaving it for a long time, or subjecting it to a high heat in a glass vessel. But as ammonia is apt to be generated in this way, M. Muriere recommends a gum made by sulphuric acid to be used in preference to glue. He gives, however, the following directions for preparing this ink with glue. Into a solution of glue he pours a concentrated solution of gallic acid, which occasions an elastic mucous looking precipitate. He washes this matter with hot water, and dissolves it in a strong solution of clarified glue. He filters anew, and concentrates it to the proper degree for being incorporated with the purified lamp black. The strongest principle of vegetable does not precipitate gallic acid when its acid is liberated, as to this by mixing the nut-galls with lime-water or magnesia. The first mode of making the ink is to be preferred. The lamp black is said to be made in China, by collecting the soot of the oil of sesame. A little camphor (about two per cent.) has been introduced in the ink of China, and is supposed to improve it. Infusorial galls renders the ink permanent on paper.

Indelible ink.—A very good ink, capable of resisting sulphuric, nitric acid, and solution with a hair pencil or of being removed by washing some of the ink made by the process of M. Berthollet, is made by mixing some of the ink made by the process of M. Berthollet with a solution of gum arabic. It writes well, and is indelible. Other indelible inks have been made, but they are all of a fugitive nature. A thickened solution of gum arabic, upon paper or cotton cloth, previously coloured with a solution of soda, and dried, is the ordinary permanent ink of the day. Before the cloths are washed the writing should be exposed to the action, or to bright daylight, which blackens and fixes the oxide of silver. It is easily discoloured by chlorine and ammonia.

A good permanent ink may be made by mixing a strong solution of chloride of platinum, with a little potash, sugar, and gum to thicken it. The writing made therewith should be passed over with a hot smoothing iron to fix it.

Another indelible ink may be prepared by adding lamp black and lumps to a solution of the gluten of wheat in acetic acid. The ink is of a beautiful black colour, at the same time cheap, and cannot be removed by water, chlorine, or dilute acids. M. Herberger gives the following directions for its preparation. Wheat gluten is carefully freed from the starch, and then dissolved in a little weak acetic acid. The liquid is now mixed with so much rain water that the solution has about the strength of wine vinegar, that is, neutral one-fifth of its weight of carbonate of soda. 10 grains of the best lamp black and 2 grains of iron are mixed with 4 ounces of the solution of gluten, and a little oil of olive added. This ink may be employed for writing on linen, as it does not resist mechanical force.

Indelible ink of Dr. Traill is essentially the same as the above.

French indelible ink is made of iodine dissolved in rosin dissolved in oil for writing with quills, and through which is passed a wire pen.
Ind. Præparata.—This is essentially a combination of lamp black,—finely divided carbon,—with oil. Mr. L. Berthollet is a combination made by him in the factory of Arts, well adapted to the ordinary uses of a good ink.

1st. It must be made strong and easy, and work sharp and clean.

2nd. It must not have too much density for the type, but have a much greater affinity for the paper, and adhere to it freely upon it.

3rd. It must dry almost immediately on the paper, but not dry at all on the type or rollers; this is a great desideratum, especially for newspapers.

4th. It should be perfectly proof against the effects of time and chemical reagents, and never change colour.

It is, however, most to be paid to the quality of the inked oil employed, and even the character of and from which the oil is obtained should not be neglected.

The inked oil is clarified from the fatty matters, and the pure oil is heated with great care at a carefully regulated temperature, and during the heating, the best yellow soap is added to give it consistency, and the required dryers are added as ordered with it. The best black is then added to form the shade of lightness, the combination being carefully examined. The black is ground up carefully with the drying oil, which has removed some what of the character of a varnish, and the ink is complete.

Gold and silver inks are prepared by grinding upon a plate of glass a gold or silver gold or silver leaf, with white honey, and this are reduced to the finest possible state of division. The honey is thoroughly washed from the leaf with spirits, and these are mixed up with good water.

INKING ROLLER. See PRINTING.

IODINE (*Iod*, *Uru*; *Iod*, *Germ*) is one of the elementary substances; it was accidentally discovered in 1812 by M. Courtois, a manufacturer of saltpetre at Paris. He found, that in the manufacture of soda from the ashes of seaweeds, the residual vessels, in which the processes were conducted, became much corroded; and in searching for the cause of this corrosion, he discovered this now important substance. It was first described by Courtois in 1813, but was afterwards more fully investigated by Davy and Gay-Lussac.

Gay-Lussac and Courtois at first looked upon hydriodic acid as hydrochloric acid, until Sir H. Davy announced the idea of its being a new and peculiar acid, and being as a substance analogous to its chemical relations to chlorine.

It was named iodine from the Greek word *ios*, violet-coloured, in account of the colour of its vapour.

Iodine exists in many mineral waters in combination with potassium and sodium.

In the mineral kingdom, iodine has been found in one or two rare urals, so in a mineral brought from Mexico, in which it is said to be combined with silver, and also in one from Sicily in combination with zinc.

It exists also in very small quantities in sea water, from which it is extracted by many sea-weeds which have therefore a concentration of it; these sea-weeds when dried and burnt yield an ash containing a small help, from which all the soda of commerce was previously obtained, but the chief value of the ash now is in account of the iodine which it yields. The following is the process most generally adopted for the extraction of the iodine from the sea-weeds.

The sun-dried sea-weed is incinerated in a shallow excavation at a low temperature, for if the temperature was allowed to run too high a considerable quantity of iodide of sodium would be lost by volatilization. The half-burned ash or kelp which remains is broken into fragments, and treated with boiling water, which dissolves about one half of the ash.

The liquid thus obtained is evaporated, when on cooling the more crystallisable salts separate, viz. sulphate and carbonate of soda, with some chloride of potassium. The mother liquor at this point contains the iodide of sodium, sulphide of sodium, sulphide and some carbonate of soda. This liquor is then mixed with about one-eighth of its bulk of sulphuric acid, and allowed to stand for twenty-four hours; carbonic and sulphureous acid, and sulphuretted hydrogen gas escape, a fresh quantity of sulphate of soda crystallizes out, mixed with a precipitate of sulphur.

The supernatant and liquor is then transferred to a leaden still, to which is adapted a double tubulated leaden head luted on with pipe-clay; it is then heated to 140° F., when hydroxide of manganese is added.

The temperature may be gently raised to 212° F., but not higher, as some chlorine would come over, and combine with some of the iodine, forming chloride of iodine.

The iodine is condensed in spherical glass condensers, each having two mouths

appears in each other, and towards the end of June the other, the red pair being fixed to the ends of the heated rods.

The iodine is purified by rectification.

The following formula represents the reaction:

The British iodine is remarkably pure, and at Glasgow, from the king of the mountains of Japan, and the volcanic source of Iceland.

Iodine is a very combustible solid, its primary form being a shining crystalline. It is however always met with in combination with foreign matter, having a greyish-black colour, a metallic lustre, and is very hot when burnt. Even at ordinary temperatures, and more especially when heated, it is usually volatile, forming an obscure blue that is colourless, very much weaker.

At 210° F. it boils, and at 347° F. it is said to be converted into a vapour which is volatile. If it is not distilled, in the presence of water, at a temperature of 210° , it is said to be the product of a sublimation.

Iodine, in its solid state, has a specific gravity of 4.93; the specific gravity of the vapour being, according to Dumas, 1.715. Iodine is only very slightly soluble in water, it requiring 7000 parts of water to dissolve it; when then it imparts a yellow colour to the solution, and is said to be that which is used for a solution with which it forms a beautiful blue compound, which is however, destroyed by heat.

Alcohol and other fluids, it does not readily dissolve; but the most powerful solvents of iodine are the vapours of the iodine. Iodine stains the skin, and must require attention, as it is very soluble in water, it stains the white rapidly, thus or even being easily dissolved by it if poured in water with it, an iodine of the world being formed.

All the compounds of iodine with the metals, and with hydrogen, are decomposed by chlorine, and even by bromine, iodine being set free. Advantage is taken of this fact in extracting the product of iodine. If the iodine exists in combination with a metal, or as hydriodic acid, no action will not form the characteristic brown liquid compound with starch, but on the addition of a little chlorine, or solution of bleaching powder, the iodine is set free and forms the blue compound with the starch. If however the iodine exists as hydriodic acid, it will not set upon starch until oxidized by some oxidizing agent, as sulphuric acid. In using the chlorine care must be taken not to use too much, as it would unite with the iodine and prevent it acting on the starch.

Iodine is used to a considerable extent in medicine; when taken in large doses it is an irritant poison, but in small doses it is a most valuable medicine, particularly in glandular swellings, and in certain forms of goitre. It is also much used in photography. The chemical symbol for iodine is I ; its equivalent number 126.9; and the combining volume of its vapour 2. — H. K. 11.

IRIDIUM. A rare white metal, found in connection with platinum and osmium. The natural combination of iridium and osmium is called the "native alloy," and on account of its hardness is used to point metal pens. See NATIVE ALLOY.

IRISH MOSS. See ALGÆ.

IRON (*Fer*, Fr.; *Eisen*, Germ.) is a metal of a bluish-grey colour, and a dull brown fracture, but it is capable of assuming a brilliant surface by polishing. Its specific gravity is 7.7. It is the most malleable of metals, and the hardest of all those which are malleable and ductile. It is singularly susceptible of the magnetic virtue, but in its pure state is brittle. When rubbed it has a sweet smell, and it imparts to the tongue a peculiar acrid taste, called chalybeate. In a moist atmosphere iron speedily oxidizes, and becomes covered with a brown coating called rust.

Every person knows the remarkable uses of this truly precious metal, it is capable of being cast in moulds of any form; of being drawn out into wires of any great strength or fineness; of being extended into plates or sheets of being bent in every direction; of being sharpened, hardened, and softened at pleasure. Iron accommodates itself to all our wants, our desires, and even our caprices; it is equally serviceable to the arts, the sciences, to agriculture, and war; the same ore forms the sword, the ploughshare, the scythe, the pruning hook, the needle, the graver, the spring of a watch or of a carriage, the chisel, the claw, the anchor, the compass, the cannon, and the bomb. It is a medium of much virtue, and the only metal friendly to the human frame.

The ores of iron are scattered over the crust of the globe with a distribution proportioned to the utility of the metal; they are found under every latitude, and every zone, in every mineral formation, and are disseminated in every soil. Considered in a purely mineral point of view, without reference to their importance for reduction, they may be reckoned to be 19 in number; namely, 1, native iron of three

The above analyses are of—1. A mass of 1 lb. weight, which fell at Bobrova, in Bohemia, in 1740. 2. A mass weighing 1,000 lbs., found in 1740, near Krasnopol, on the Yagora. 3. The meteor of Veszto near Hungary, from Timisoara, which weighed 100 lbs. 4. A mass of 71 lbs. weight, which fell at Hradec, near Agram, in Croatia, on 5th May, 1771. 5. A mass in the Hainan Museum, found in 1775, in the plain between the Great Fish River and Great River, in the Canton of Yunnan, originally weighing 10 lbs. 6. Found at Lobsenz in Hungary, weighed in 1841. 7. From Chertsey in Australia. 8. From Lobsenz. 9. Is a more recent analysis of the same. 10. From Lobsenz in North America. 11. From Bittsburg, near Treuen which weighed about 400 lbs.

According to Shepard (*American Journal*) the fall of meteoric stones is confined principally to two tracts. The one belonging to America lies between 23 and 41° N. lat. and is about 18° in length. Its direction is from S. W. to N. E., following the general line of the Atlantic ocean. Of all the occurrences of this phenomenon since the last 200 years, 400 per cent. have taken place within these limits, and usually in the neighbourhood of the equator. The spots of the earth, however, with the exception that it extends to the North Pole, is bounded by the same degree of latitude, and follows a similar course, and therefore it is not far from true that the whole of the American tract. Of the remaining tract of 18°, which lies between 41° and 50° N. lat. and 100° and 120° W. long., it is estimated that half of the same which extends along the Atlantic.

The most remarkable specimens of meteoric iron are, that found by Dr. Raimond Celsa, in Tucuman, in South America, in 1764, weighing 100 lbs.; that discovered in 1764 on the Ilha de Itabora, in Brazil, estimated to contain 17 parts of Fe, and to weigh 17,000 lbs.; and that of the Ilha de Itabora in Louisiana, weighing 100 lbs., and presenting distinct octahedral crystals.

c. 1. *Native Steel-Iron*.—This substance has all the characters of cast steel; it occurs in a kind of small brittle nodules, with a finely crystalline and a fracture usually fine grained. It is brittle when heated by the fire, and is easily fused in under the hammer. At Mittern, about 10 miles west of the village of Hohenberg, near Nory, department of the Allier, is a spot where there had been a mine of burning coal. A mass of 10 lbs. 6 oz. of native steel was discovered in that place, besides a great many small pieces.

2. *Mispickel, Diarsenide of Iron, Arseni-ferrite*.—This mineral is found massive, granular, or columnar, and disseminated. It is brittle, with an uneven fracture; colour, a very white, crystalline grey, with a grey drusey appearance; specific gravity 6–6.2. When heated in a closed tube it yields first a red, then a brown sublimation of sulphur, and then metallic arsenic. Some varieties contain silver or gold, in others part of the iron is replaced by cobalt. Viewed as a double sulphide and arsenide of iron, its formula would be $\text{FeS}_2 + \text{FeAs}$, which requires iron, 27.5; sulphur, 12.9; arsenic, 46.6. A specimen analysed by Plattner gave, iron, 34.46; sulphur, 20.7; arsenic, 45.46. Mispickel is common in the mines of Freiberg in Saxony, and in the tin mines of Hohen, Silesia, and in Cornwall. It is of no use as an ore of iron, but it is occasionally worked for the silver it contains, and as an ore of arsenic.

3. *Yellow sulphuret of iron; Prismatic iron pyrites, or Marcasite*.—The bronze or brass yellow colour enables us to recognize this mineral. At the blowpipe it gives off its sulphur, and is converted into a globule of malleable by the hammer. It is brittle, with a conchoidal or uneven fracture. Sp. gr. 4.9–5.1. It is soluble in water, and with deposition of sulphur, but is scarcely affected by hydrochloric acid. It is a disulphide of iron (FeS_2), 46.7 iron, 23.3 sulphur. Plattner found 47.3 iron, 22.7 sulphur; and Wernicke, 46.4 iron, and 23.6 sulphur. It is very liable to decomposition, being sometimes oxidized to sulphate of iron, and sometimes to hydrated peroxide, the sulphur becoming altogether eliminated. It is one of the most common minerals in rocks of all ages and classes; it occasionally contains both gold and silver. It is used for the manufacture of sulphur, sulphuric acid, and alum, but as an ore of iron it has no commercial value.

4. *Hexahedral iron pyrites, or pyrite*.—This mineral is distinguishable from the former only by its colour and form of crystallization, and was hence till lately confounded with it by mineralogists. Its surface is often radiated.

5. *Magnetic iron pyrites, pyrrhotine, the magnetite of the Germans*.—This mineral occurs chiefly in the igneous and crystalline, or older stratified rocks, in veins with various ores. Its colour is between brown yellow and copper red, with a pinchbeck-brown tarnish, streak greyish-black, and more or less magnetic. When heated in an open tube it yields sulphurous fumes, but no sublimation, before the blowpipe on charcoal in the reducing flame it fuses to a black strongly magnetic globule; it is

in by sulphur, and evolving sulphur hydric acid, and depositing sulphur. A. G. H. has shown several ways in which a large quantity of sulphur may be combined with the sulphur of FeS₂, and he adopts for it the formula FeS₂ + 4FeS, agreeing with the analysis of the 44 iron and 40 sulphur, which agrees very closely with the analyses that have been made by S. G. J. R. H. Rose, and others.

6. *Iron ore of iron, Magnetite, or oxidized iron ore.* — This very rich and valuable ore occurs especially in igneous or metamorphic rocks, either in distinct crystals, or, as in many basalts, disseminated through the mass, when it frequently imparts magnetic properties to the rocks, especially to greenstone, serpentine, or basalt. It also forms veins in granite, in chlorite, mica, hornblende, and clay slate, or basalt. It also forms veins in granite, in chlorite, mica, hornblende, and clay slate, or basalt. The largest known masses occur in the northern parts of the globe, in Scandinavia, Lapland, Siberia, and North America. Less extensive masses occur in the Harz, in Saxony, Ilmenau, Styria, and in Southern Europe, in Elba and Spain. *Magnetite* is the most important ore of iron in Norway, Sweden, and Russia. The Hammeberg mine in Sweden, wrought in an open quarry 150 feet broad, and 200 feet deep, furnishes the fine Öregrund iron, largely imported into England for the manufacture of steel. Some highly magnetic varieties, especially from Sweden and the Harz, form natural magnets, possessing disintegrating power. Magnetite ores are fused with extreme difficulty; it is not acted upon by nitric acid, but when powdered is soluble in hydrochloric; its specific gravity varies from 4.24 to 4.4. The chemical formula of pure magnetite is Fe₃O₄, containing 72.4 per cent of iron, and 27.6 of peroxide of iron, or of 24.0 iron, and 27.6 oxygen, which agrees closely with the analyses of Berzelius, Kramm, and Karsten.

Two specimens of magnetic iron ore from Cornwall had the following compositions (Dr. Neill):

Water	2.50	3.20
Peroxide of iron	28.00	18.00
Peroxide of iron	41.40	60.50
Oxide of manganese	1.6	2.6
Alumina	3.20	3.60
Lime	0.60	0.56
Magnesia	1.00	1.53
Sulphur acid	0.04	0.04
Phosphoric acid	0.50	0.57
Insoluble residue	24.20	9.40

9.60 98.95

7. *Hematite, Spanish iron, Iron ore; Hematite iron ore.* — This ore has a metallic lustre, and is black to steel grey, but often tarnished; the light transmitted through the thin edges of the crystals appears of a beautiful red colour. Its powder is always of a well marked brown red hue, passing into cherry red, which distinguishes it from the black oxidized ore; its fracture is conchoidal or uneven; it is brittle, and its specific gravity is 5.2. Its chemical composition is Fe₂O₃, 70.03 iron, and 29.97 oxygen, but it sometimes contains oxide of titanium, or titanate acid, rhombic, or silica; in the red-tinged flame of the blowpipe, it becomes black and magnetic.

Hematite is one of the most abundant ores of iron. The specular variety occurs chiefly in the older crystalline rocks in large beds or veins. The mines of the island of Elba celebrated from antiquity, still furnish the finest crystals, which occur in streaks of the massive variety along with pyrites and quartz; fine crystals are likewise produced from St. Gothard, Framont, in the Vosges mountains, the Harz, Altenberg in Sweden, and from Katharinenburg in the Ural. Beautiful specimens of the massive variety occur at Zorge and other parts of the Harz, at Tiscroft in Cornwall, Tavistock in Devonshire, in Wales, Cumberland, and Perthshire. It also occurs in volcanic rocks, as in Auvergne, on Vesuvius, Aina, and the Lipari Islands, especially Stromboli, where some fine crystals, three inches broad and four long, have been procured.

8. *Red hematite.* — These ores are found in the greatest abundance in the mountains or carboniferous limestone formations. The most abundant deposits in this country are those of Lancashire, Cumberland, and the Forest of Dean, where the ore exists in almost unlimited quantity. In the latter locality they were worked most extensively at a very early date, and though as a class they are not rich, yet from the great masses in which the ore is found, its cost of production is very low, about 2s. to 2s. per ton (*Blackwell*). The iron made from the Forest of Dean ore, is of

the quality which red-ore is generally substituted for the substitution of the place. This ore is raised extensively for shipment to the iron works of South Wales.

The varying quality of the Forest of Dean ore is shown by the following analysis (Dr. Nock).

	I.	II.	III.	IV.	V.
Water	7.15	2.60	2.60	2.11	2.70
Carbon	37.00	37.32	37.50	14.18	14.40
Carbonaceous	18.00	18.70	20.00	17.19	18.00
Oxide of iron	-	-	-	-	200
Peroxide of iron	4.00	12.10	12.00	10.70	10.50
Alumina	6.00	2.00	-	1.00	-
Sulphuric acid	trace	trace	trace	trace	trace
Phosphoric acid	trace	trace	trace	trace	trace
Insoluble residue	5.1	2.7	3.00	5.10	1.00
	100.00	100.00	100.00	100.00	100.00

The hematite of Whitehaven occurs in the carboniferous limestone near the outcrop or surface edge of the slaty rocks upon which that formation rests. The greater part of the excavations from which it is extracted are subterranean, and it is necessary to enter the mass of iron ore in which the workings are carried on, that it is difficult in such situations to obtain a clear idea of the nature of this important deposit. (Harrison *Geol.*, 67, 214) Some of the hematite of the Whitehaven district is exported on the spot, at the Chester Moor and Workington works, and 201,700 tons are sent into the iron-making districts. In the year 1852, 100,000 tons were sent away by road and railway from the Ulverston district, and no less than 600,000 tons of hematite were exported during 1855 (*Hunt*), for the supply of Staffordshire, South Wales, and other districts from these two localities. Considering its quality, it brings but a low price, viz. from 11s. 6d. to 12s. 6d. per ton.

The following analyses of some carefully selected samples of the hematite of the carboniferous limestone are by Messrs. Park and Spiller. (*Memoria of the Geological Survey of Great Britain. The Iron Ores of Great Britain. Part I.*)

	Central Main.	Clonsilla Main.	Ulverston Main.	Ulverston Main, road.
Peroxide of iron	93.18	90.36	86.50	94.20
Peroxide of manganese	0.24	0.10	0.21	0.20
Alumina	-	0.37	-	0.51
Lime	0.07	0.71	2.77	0.05
Magnesia	-	0.06	1.45	trace
Phosphoric acid	trace	trace	trace	trace
Sulphuric acid	trace	trace	0.11	0.00
Bisulphide of iron	trace	0.00	-	0.00
Water, hygroscopic	-	-	-	0.00

Carbonic acid	-	-	2.00	-
	101.15	100.20	100.00	100.00

The carboniferous limestones of Derbyshire and Somersetshire also contain spots and deposits of hematite, though of a quality not equal to those of Lancashire; the same ore is also met with in the Devonian series of Devon, West Somerset, and Cornwall.

9. *Brown Hematites; Brown oxide of iron; Hydrous oxide of iron.*—This species affords always a yellow powder, without any shade of red, which passes sometimes into the bistre brown, or velvet black. At the blowpipe it becomes brown, and very attractable by the magnet; but after calcination and cooling the ore yields a red

powder, which stains paper nearly as red as the hematite does, and which is much employed in polishing metals. All the yellow or brown oxides contain a large proportion of water in chemical combination. There are several varieties, which may be black, red, reniform, subcubic, and fibrous shapes. In many countries this is one of the most powerful and valuable ores of iron; in the United States it is supplied by the greater number of the French iron works. In that state it is found in Normandy, Berry, Harz, and, Lorraine, and many other places. It is this ore which exclusively supplies the French iron works. It is found in this country in considerable quantities at Aston, Moor and Durham, but is only used to a limited extent, on account of its combination with sand and lime.

The iron which the brown hematite produces does not at present stand high, it is inferior to cast-iron, but has a great tendency to cold and brittleness, and is most suitable for ordinary purposes. — *See* *Journal*.

The chemical composition of pure brown hematite is $2\text{FeO} \cdot 3\text{H}_2\text{O}$; 55 per cent of iron (= 60 iron) and 14.4 water. Yellow ochre (pyrolusite) is considered by Haüy to be a distinct species, a specimen analysed by him contained 81% peroxide of iron, and 18.4 water, corresponding to the formula $\text{Fe}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$. The iron ore is also a hydrated oxide of iron; it occurs chiefly in large masses, in the iron ore, especially in the level strata of Southern Germany and Sweden. In Britain it is most abundant in the northern and western islands of Scotland. It is generally very impure, sometimes containing as much as 10 per cent of phosphoric acid, which renders it almost useless for iron making purposes. The strata, or cages of iron ore, are also a variety of the ore, in breaking the balls so round, they are observed to be composed of concentric strata, the outer layers being very hard, but the interior becoming progressively softer towards the centre, which is usually earthy, and of a bright yellow colour, sometimes, however, the centre is quite empty, and contains only a few drops of water. These occur in abundance, often even in continuous beds, in secondary mountains, and in certain argillaceous strata, when mined they yield a good iron.

Some of the brown hematites contain a large percentage of manganese. Their general composition is illustrated in the following analyses (Dr. Nord).

	I.	II.	III.	IV.
Water	12.5	12.80	12.40	12.30
Oxide of manganese	3.9	9.60	8.50	11.20
Lime	—	—	—	—
Magnesia	1.72	1.10	1.70	1.40
Alumina	1.20	.93	1.10	1.04
Peroxide of iron	69.57	69.48	67.77	66.98
Sulphuric acid	0.11	0.11	0.10	0.11
Phosphoric acid	1.01	1.00	1.12	1.03
Loss on residue	12.00	9.20	9.00	11.20
	100.4	101.0	99.70	100.25

10. *Purified hydrate of iron; Pyrite; Limonite.* — This mineral occurs in many old mines especially those near Freiberg, and also at Schneeberg in Saxony, Poland in Silesia, and Blatitz in Bohemia. It is probably a product of the decomposition of mica. Its composition, according to the analysis by Stromeyer being $\text{FeO} \cdot \frac{1}{2}\text{H}_2\text{O}$, $\text{AsO}_3 \cdot \frac{1}{2}\text{P}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$ = 35 peroxide of iron, 26 arsenic acid, 9 sulphuric acid, and 30 water. According to Freudenberg, it is first fluid, and gradually separates in a solid form. In external characters it agrees with *Dindurite*, which is $\text{Fe}(\text{P}_2\text{O}_5) \cdot 4\text{Fe}(\text{P}_2\text{O}_5) \cdot 32\text{H}_2\text{O}$, according to Gmelin from Mattner's analysis, viz. peroxide of iron, 35.5; phosphoric acid, 14.8; sulphuric acid, 15.15; water, 30.35.

11. *Yenite; Limonite; Hemerite or thronite; Nötreite. Pingrite; and Chloropal,* are rather rare minerals, composed of peroxide of iron and silica; the former contains about 12 per cent of lime; the others are destitute of this earth, but contain from 10 to 20 per cent of water; the amount of silica in these minerals ranges between 30 and 40 per cent.

12. *Carbonate of iron; Sparry iron; Spathose iron; Sphäroclerite; Spathoersterite.* — This important species has been divided into two varieties; spathose iron proper, and the compact carbonate, the clay iron stone of the coal formation. Sparry iron appears to range through nearly the same series of formations as the anhydrous hematites; it occurs in beds and masses often of immense extent, especially in Styria

and Carthage. In the *Erzkönig*, near Jauernitz in Saxony, it occurs in green, and is wrought into iron bars. The *Smithy* and *Blackband*, near Birmingham, are variety of *lump*, and *Black* is a *Wagon* iron, or *large* variety, which is *Anthracite* and the *Black* forms large veins in graywacke or Devonian limestone. Other very extensive deposits of this ore are found in the Pyrenees, and the Basque provinces of Spain, as near *Kilma*; and at *Pau* near *Bordeaux* in New Gascony. Most of these localities yield fine crystals, and these also occur in certain veins at *Journival* in Belgium, *Freiburg* in Saxony, *Kilmuck* in the Harz, *Isère* in the *Dauphiné*, *Almadén* in *Cambria*, and in many of the mines of *Cornwall*, particularly the rare hexagonal prisms (*Nov.*). In England the crystalline carbonate of iron occurs in the Devonian of South Devonshire and North Devon, and in the earlier Silurian limestones of North Devon.

The specific gravity of sparry carbonate of iron varies from 3.5 to 3.7. Its positive form is like that of carbonate of lime, as shown elsewhere. Whilst changing this form, its crystals are composed of containing various quantities of carbonate of lime, till it passes wholly into a mineral. When heated before the blowpipe it turns brown without melting, and becomes attracted by the magnet after being slightly heated in the flame of a candle. Even by a direct exposure to the air after exposure from the magnet, it also becomes the same brown, but not without improving the magnetic quality; after long exposure to the air it becomes wholly converted into hydrated hematite.

The variations in composition of this important mineral are shown in the following analyses.

	Sparry Hematite	Pyritic Pyromet.	Iron Lump.	Black band Lump.	Heavy black band	Nov. black band
Peroxide of iron	63.75	50.00	47.85	54.41	57.03	52.56
Benzoic acid of iron	-	-	-	-	5.15	-
Peroxide of manganese	0.75	0.50	1.77	25.41	12.00	4.00
Stagnation	0.25	0.70	0.00	-	4.52	2.41

This ore, viewed as a metallurgical object, is one of the most interesting and valuable that is known; it affords *natural steel* with the greatest facility, and accommodates itself best to the Catalan smelting forge. It was owing in a great measure to the peculiar quality of the iron which it produces that the excellence long remarked in the cutlery of the Tyrol, Styria, and Carinthia was due. It was called by the older mineralogists, *steel ore*.

Coal measure iron stones.—The compact carbonates of iron has no relation externally with the sparry variety. It comprehends most of the clay ironstones, particularly those which occur in flattened spheroidal masses of various sizes among the coal measures. The colour of this ore is often a yellish brown, reddish grey, or a dirty brick red. Its fracture is close grained, it is easily scratched, and gives a yellowish brown or grey powder. It adheres to the tongue, has an odour slightly effluvescent when breathed upon; blackens at the blowpipe without melting, and becomes attracted by the magnet after calcination. The ironstones of the coal formation admit of a natural division into two great classes, viz. the *gray*, and the *blackband* or *carbonaceous*. The earthy or lithoid carbonates occur in some regions in the upper limestone shales, and they extend upwards through the coal measures proper towards their higher limits; they likewise occur in extensive beds in the Jurassic formation, particularly in North Yorkshire; near the upper limit of the lias, or base of the oolites proper; and again higher, as nodules and perhaps as beds, in the middle oolites, or Oxford clays. They are also found extensively as courses of nodules in the Wealden series, and as beds in the green sand. When these gray carbonates contain lime in abundance, and when clay is not largely present, they are sometimes changed by atmospheric influences into hydrated hematites; in Northamptonshire, for example, and widely in France. The only great coal fields in Great Britain in which these ores do not occur in sufficient abundance to form the basis of a large production of iron, are those of Northumberland and Durham, and of Lancashire. The great importance of the argillaceous and blackband ironstones of our coal-fields is clearly shown by the fact, that they supply at least *nine-tenths* of the entire iron produced

Remarks. They vary considerably in their percentage of iron, which is generally not more than 30 per cent., but occasionally ranges as high as 40 per cent. They are rarely used where they contain less than 20 per cent. The varying proportions of iron, silica, and alumina which they contain is shown in the following analysis of the ore from different localities.

Iron per cent	99.00	99.00
-------------------------	-------	-------

The quality of the iron produced from the argillaceous ironstone is extremely good, provided the coals used for smelting are good. The ore is always used in a calcined state, by which it loses in weight about one-third or one-fourth, the loss consisting of carbonic acid and water. The production of iron in South Wales, North Staffordshire, Northumberland, and Durham, rests almost entirely on the great beds of this mineral. In Scotland the ore almost exclusively used is the *blackband* or *carbonaceous ironstone*, immense deposits of which occur likewise in the coalfield of North Staffordshire; this variety sometimes contains as much as 25 to 30 per cent. of carbonaceous matter, but is usually free from much earthy matter; it often contains phosphoric acid in quantity sufficient to communicate to the iron the quality of cold shortness. The discovery of this class of ironstone in Scotland by Mr. Musket in 1801, and the power of using it at once in the furnace by means of hot blast, constituted a new era in the manufacture of iron, and gave to Scotland, till then an iron making district of little importance, the pre-eminence over all others, for the production of soft fluid iron, best suited to ordinary foundry purposes.—*Blackwell.*

In France the clay carbonates of the coal measures are only found of sufficient value to work in three localities, — in the coalfields of the Gard, of the Aveyron, and of a very limited extent in the coalfield of the Loire, near St. Etienne.—*A. Dickson.*

In America it is largely distributed over Pennsylvania, Maryland, Virginia, Ohio, Illinois, North Carolina, and Kentucky; but from the difficulties of working it in the blast furnace, it is not in general use.

13. *Phosphate of iron; Blue iron; Vivianite.*—The colour of this mineral varies from indigo-blue to blackish green; the earthy variety is white in the beds, but changes blue on exposure to the air; heated in a closed tube it yields much water, attumescens, and becomes spotted with grey and red; before the blowpipe, if charred, it fuses to a grey, shining, metallic granule. Transparent indigo-coloured crystals of phosphate of iron, sometimes an inch in diameter and two inches long, occur with iron and copper pyrites in the tin and copper veins at St. Agnes in Cornwall. It was first found in the auriferous veins at Vorapatak in Liebenberg; the earthy varieties are very common in Cornwall, Styria, North America, Greenland, and New Zealand. A specimen from St. Agnes, Cornwall, gave Stromyer—phosphoric acid, 31.18; protoxide of iron, 41.27; water, 27.48; and another from New Jersey yielded to Rammeisberg—phosphoric acid, 30.40; protoxide of iron, 33.91; peroxide of iron, 12.00. It is sometimes used as a pigment, but is of no use as a smelting ore.

14. *Siderite*, *from the green sand*.—*Siderite* is formed by the oxidation of sulphuret of iron, and is a crystalline mineral of a dark green color.

15. *Chromite*, *from the black chromite*.—This mineral occurs in crystalline form in the black chromite rock. It was first discovered at Gams, near Vardø, in the Fennoscandia, and is found in Saxony, Silesia, Bohemia, and Norway, and in large quantities in the Fennoscandia, near Kongsberg. It is a black mineral, with a metallic luster, in a brownish-black, streak yellowish to reddish brown. A specimen from Norway, analysed by Von Koenig, gave protoxide of iron, 24.4; peroxide of iron, 14.1; alumina, 9.02; magnesia, 2.18; and silica, 4.31; a specimen from Chester in Pennsylvania, yielded to Sjöberg protoxide of iron, 24.4; peroxide of iron, 14.1; alumina, 13.6; and silica, 10.0. It is used in the preparation of various pigments. For the treatment and use of the ore, see Chromite.

16. *Malachite*, *from the green sand*.—This mineral, which is rather rare, occurs in great beauty associated with copper ore in Cornwall; it has an olive green color, and is rather brittle. Its composition, according to the analysis of Berzelius, is, silica, 1.04; peroxide of iron, 20.1; protoxide of iron, 12.6; water, 2.9.

17. *Malachite*, *from the green sand*.

18. *Chromite*, *from the brown coal*.—This mineral, which occurs in the form of crystals, is found in the brown coal at Kongsberg, near Oslo, in Bohemia, and at the same place in Norway, according to the analysis of Hammerberg, of silica, 1.44; peroxide of iron, 11.13; and water, 1.47.

19. *Titanite*, *from the green sand*.—This variety of iron is variously found, in the form of the iron ore, in the green sand, at Gams, in Silesia; in the green sand at Kongsberg in Southern Norway; and in the green sand, at Trondheim, and Kongsberg, near Arendal. It is extremely infusible, and is considered injurious when mixed with other ore. Its chemical composition, according to H. Rose and Scheerer, is a combination of peroxide of iron, and blue oxide of titanium, in various proportions, the specific gravity increasing with the amount of iron.

20. *Titanite*, *from the green sand*.—occurs with tin ore, forming fine crystals, at Austerlitz, in Saxony; at Schönbach, in Bohemia; and in France, in quartz veins. In Cornwall, near Redruth, it is sometimes so abundant as to render the iron ore wholly valueless. An analysis of a specimen from Cumberland gave Berzelius tangent acid, 75.77; protoxide of iron, 15.32; protoxide of manganese, 6.72; and silica, 1.25.

There is abundance of evidence that iron was well known in the early ages, and was applied to various useful purposes. The earliest method of working the furnace when it was first used, was to have been by exposing them to the wind (the furnaces, performed with this, were built on ruins, and could only be worked when there was a strong breeze; the fire was regulated by opening and shutting the apertures. Mr. Park, in his "Travels in Africa," the following interesting account of an iron-making operation in Katsina, at which he has witnessed "The iron ore was broken into pieces the size of a hen's egg; a bundle of dry wood was first put into the furnace, and covered with a considerable quantity of charcoal; over this was laid a stream of iron ore, and then a layer of charcoal, and so on until the furnace was quite full. The furnace was a circular tower of clay, about 10 feet in height and 7 in diameter, perforated in two places with withes, to prevent the clay from cracking and falling to pieces by the violence of the heat. Round the lower part, on a level with the ground, but not so low as the bottom of the furnace, which was somewhat conical, were made seven openings, into each of which were placed three tubes of clay, and the openings again plastered up in such a manner that no air could enter the furnace but through the tubes, by the opening and shutting of which the fire was regulated. The fire was applied through the top of the tubes, and blown for some time with bellows made of goat's skin. The operation went on very slowly at first, and it was some hours before the furnace appeared above the furnace; but after this it burst with great violence all the first day, and the people who attended put in at times more charcoal. On the day following the fire was not so fierce, and on the second night some of the tubes were withdrawn, and the air allowed to have free access to the furnace; but the heat was very great, and a bluish flame rose some feet above the top of the furnace. On the third day from the commencement of the operation all the tubes were taken out, the ends of many of them being vitrified with the heat, but the metal was not removed until some days afterwards, when the whole was partly cool; part of the furnace was then taken down, and the iron appeared in the form of a large irregular mass, with pieces of charcoal adhering to it. It was sonorous, and when any portion was broken off, the fracture exhibited a granulated appearance like broken steel."

That the iron ores of Scotland and the Cornish mines were extensively worked by the Romans during the period of their power in Britain, appears from the numerous beds of iron miners that have been discovered in the Forest of Dean; it is probable that that was the principal seat of their manufactures, as the iron ore is to be found in the form of cinders, and even, have been known to be varied in Yorkshire and in other counties. During the reign of William the Conqueror, the iron was the chief article of the trade of England that was chiefly carried on, the Forest of Dean supplied the iron.

It is remarkable, when the art of smelting was first discovered, that the first furnace found to have been first used in England by Edward the Third, who made them in the invasion of Scotland in 1327, at Croy, and at the siege of Calais in 1346. These furnaces were not however cast, but were constructed in the same purpose to improve construct their furnaces; a number of iron bars fitting as close as possible to each other were arranged round a cylinder of wood, and were then bound together by driving in logs; the wood being driven out, there remained an iron pipe which formed the furnace. This mode was superseded by casting the furnace of iron.

During the 14th and 15th centuries, iron was not only wrought into the country from Germany, Prussia, and other places, but also from Spain; but as several improvements in the manufacture had taken place in the north of the present of England, it was made to work in the south of the 16th century, producing the improvement of a new article manufactured in the country in iron and steel. During the reign of Elizabeth, the consumption of iron by the iron furnace was so great that it was deemed necessary to enact laws to prohibit the export of iron furnaces, and to prevent the selling of timber for fuel; persons concerned in the manufacture of iron were consequently compelled to turn their attention to the finding of some substitute for charcoal, and in the reigns of James the First and Charles the First many attempts were made to smelt iron with pit-coal, but without success; the consumption was the entire and almost of iron making in many parts of the country, and a great decrease in the manufacture in others; so much so indeed was the failure of all the experiments made to substitute pit coal for charcoal, that all attempts were abandoned till the early part of the next century, when pit coal was first used in 1711 by Mr. Abraham Darby in his furnace at Coalbrook Dale; and in the 4th volume of the Philosophical Transactions, published in 1747, it is stated, that "Mr. Forth, from iron and coal, both got in the same Dale (Coalbrook), makes iron brittle or tough as he pleases, there being cannon thus cast so soft, as to bear turning like soft iron." Notwithstanding, however, the establishment of the fact that iron ore could be smelted, and iron manufactured with pit-coal, and although great efforts were made, by increasing the column of blast, by the substitution of steam power for that of horses and human labour, there appears to have been a steady and progressive improvement in the quantity of iron produced in this country; and recourse was had to foreign markets, particularly to those of Sweden and Russia, for the necessary and increasing demand. Thus, the imports of iron between the years 1711 and 1776, were as follows:—

									Tons.
1711	to	1715	-	-	-	-	-	-	15,643
1729	"	1735	-	-	-	-	-	-	23,501
1750	"	1755	-	-	-	-	-	-	34,072
1761	"	1766	-	-	-	-	-	-	4,000

In 1740 there were only 59 blast furnaces in work in England and Wales, the total make of which amounted to not more than 17,350 tons, being an average of 294 tons per annum for each furnace, a quantity very little exceeding that sometimes made in a single week in some of the furnaces in Wales at the present day.

The earliest contrivance for throwing a powerful and constant blast into the furnace was a forcing pump, worked by a water wheel or by a steam engine; and it appears that the first cylinders, at least of any magnitude, were erected at the celebrated Carron Iron Works in the year 1766 by Mr. John Smeaton. These cylinders were four feet six inches in diameter, exactly fitted with a piston, moved up and down by means of a water wheel; in the bottom of the cylinder was a large valve, like that of a bellows, which rose as the piston was lifted up, and thus admitted the air into the cavity of the cylinder below. Immediately above the bottom was a tube which went to the furnace, and as it proceeded from the cylinder, was furnished with a valve opening outwards. Thus when the piston was drawn up, the valve in the bottom rose and admitted the air that way into the cylinder, while the lateral valve shut, and prevented any air from getting into it through the pipe. When the piston was thrust down, the valve in the bottom closed, while the air, being compressed in the cavity of the cylinder, was violently forced out through the lateral tube into the

There were four of these large cylinders applied to blow the furnace, and it was contrived, that the strokes of the pistons became alternately, producing an almost non-stop blast of air, of triple or quadruple quantity, was thus obtained, and effects equivalent to those given by the process followed. The same furnace that formerly yielded one and twelve tons weekly now would produce forty tons in the same period, and in the average in one year 1,500 tons of metal (Switzerland); and such was the impetus given to the trade by this unexpected source of a powerful blast with pit-coal, that in 1790 the manufacture of pig-iron in England, Wales, and Scotland amounted to 61,000 tons, being an increase of 30,750 tons on the quantity annually raised previous to the introduction of pit-coal.

A new era in the history of the iron manufacture may be considered to have been established in 1780, by the introduction of the double power engine of James Watt, the singular and increased effects of which powerful machine were soon felt in most of the iron districts: the proprietors of furnaces greatly increased their make, and fresh capital was embarked in the trade. In the short period of eight years, the manufacture of pig-iron was nearly double, being in the year 1786, (according to the return sent to the chairman of the committee of the House of Commons, on the subject of the coal trade, when Mr Pitt had it in contemplation to add to the revenue by a tax upon coal at the pit mouth,) 122,79 tons, from 121 furnaces—104 English and Welsh, and 17 Scotch; the English and Welsh furnaces producing an average of 1,018 tons each per annum, and the Scotch furnaces 946 tons. In 1804, the number of furnaces in Great Britain was 173, and the make 288,206 tons of pig-iron. During an interval of ten years, of 1814-23, the average produce of each had risen to 1,646 tons. In this year great exertions were made in the iron trade, in consequence of the proposal of Lord Henry Petty to levy, as a war tax, a duty of 4s. per ton on pig-iron; but introduced a bill into the House of Commons having this object, and succeeded in carrying it, notwithstanding a powerful opposition, by a majority of ten members; the measure was however abandoned.

In France, in 1801, the quantity of cast iron produced amounted to 140,000 tons from 100 blast furnaces, of which only one (that of Creusot) was worked with coke. In 1804, a description of the English process of making iron was published by order of council, by M. de Bonnaud (an engineer of mines); another engineer of mines (M. de Gualbert), after having passed several months in England, established at St. Etienne the second blast furnace in France, wherein the minerals were treated in the same manner as the English, and in which coke was employed; but the difficulties he had to encounter proved a bar to his success, and he is said to have died prematurely from the grief and trouble which the enterprise occasioned him (Scarb. &c.) The employment of pit-coal in the manufacture of iron received a very slow development in France, for in 1818 the quantity of cast iron made with coke was very small, and no wrought iron was prepared with pit-coal; in 1824 not more than 3,000 tons of cast iron were made with coke, but in 1828 it had risen to 17,000 tons. Though this did not amount to a tenth of the whole produce, nevertheless the quantity of bars made with pit-coal amounted in this year to 49,000 tons, being nearly one-third of the total manufacture of wrought iron.

Cast iron, using that term in the sense in which it is now understood, must have been wholly unknown to the ancient metallurgists, for even in the smelting of their poorer ores, where they urged their ferrous with the greatest heat they could command, using probably lime as a flux, the red-hot metal was allowed to cool in the bed of the furnace, and was never run into pigs as in the modern practice; their best iron was produced in one operation and after cooling and separating the scoria, it was forged at once into tough hard bars under the tilt hammer. The time and fuel consumed in these ancient methods was enormous, and the iron that remained in the scoria, amounted to fully one half of the original metallic contents of the ore.

The modern process of iron smelting differs materially according as the fuel employed is charcoal or pit-coal. As an illustration of the method adopted when the former is used, the following details of the manufacture of the celebrated "Oregrund iron" may be taken, premising that the operations vary in a few particulars in other countries where different kinds of ore are dealt with. The Oregrund iron is made from the magnetic ironstone of Dannemora in Sweden. The ore, in moderately large pieces such as it comes from the mine, is first roasted. For this purpose an oblong coffin of masonry, 15 feet long, 15 feet wide, and about 6 feet in depth, open at top, and furnished with a door at one of its smaller extremities, is entirely filled with logs of wood over this the ore is piled to the height of from 5 to 7 feet, and is covered with a coating of small charcoal, almost a foot and a half in thickness. Fire is then communicated to the bottom of the pile, by means of the door just mentioned.

and in a short time the combustion spreads through the whole mass, the small quantities of pyrites that still remain in the ore, and by the combination of the sulphur, the necessary gas being set off, and the ore, from being very hard and dense, becomes easily pulverizable. In the course of twenty days from the beginning of combustion, and the ore being sufficiently used is transformed to a shaggy mass, where it is poured dry, and afterwards rolled through a sieve of iron, where it is reduced to a fine layer, or to a fine dust. It is then ready to be melted. The resulting slag is a strong quadrangular piece of iron, the internal fibres of which, though simple in form, are very much disturbed. It may be considered as given, as representing the regular transformation of the ore, and from the lower it is conveyed into the upper, and is put off by the apertures, through the upper end of which the blast of wind from the furnace is admitted into the furnace, and from the lower the melted matter, both scoria and metal, is discharged from time to time at the pleasure of the workmen.

The furnace is kept filled with charcoal, above, and well heated, after which other rate charges are added of ore, either whole, or mixed with fragments of the former any (see fig. 1) and charcoal, the blast is let on, and the process is then being to keep the charcoal in a good state, the upper part of the furnace, is usually heated as long as it arrives in the form of the blast, where it remains in a hot state to the bottom of the furnace covered with a melted slag. Part of the slag that flows to the lower part of the furnace is usually removed, to allow the metal to flow out, and at the end of every such hour the iron is left in the furnace a half of an hour, when it forms from the bottom to the top. As soon as the iron has flowed out, the aperture is closed again, and then the furnace is kept in constant activity during the first six months of the year, the other six months are employed in repairing the furnace, making the metal, and reducing the regular process of wind and iron. The next process for converting the pig iron into a bar iron, for the purpose of a furnace is made up of, consisting of a large hearth, with a sloping front, and from ten to twelve inches below the level of the hearth. This cavity is filled with charcoal and iron, and in the centre of the sloping front a large opening is made into the furnace, and the iron is then let in, and the pig iron being placed in the very focus of the heat, soon begins to melt, and as it begins, runs down into the cavity below, where, being out of the direct influence of the blast, it becomes solid, and is then taken out, and reduced to a bar iron. The cavity being then filled with charcoal, it is then fired a second time, and after that, a third time, the whole of these three processes being usually done in between three and four hours. As soon as the iron has become solid it is taken out, and very slightly hammered to free it from the adhering scoria; it is then returned to the furnace, and placed in a corner, out of the way of the blast, and well covered with charcoal, where it remains, till, by further gradual cooling, it becomes sufficiently compact to bear the tilt hammer. Here it is well beaten till the scoria are forced off, and it is then divided into several pieces, which, by a repetition of heating and hammering are drawn into bars, and in this state is ready for sale. The proportion of pig iron obtained from a given quantity of ore is subject to considerable variation, from the difference in the metallic contents of different parcels of ore and other circumstances; but the amount of bar iron that a given weight of pig metal is expected to yield is regulated very strictly, the workmen being expected to furnish four parts of the former for five parts of the latter, so that the loss does not exceed 20 per cent.

In some parts of America, particularly in the states of Vermont and New Jersey, the Catalan forge is extensively employed for smelting the rich magnetic ores which

there abound. The form of this forge (which is nearly uniform every where), and the manipulation with it in America, is thus described by O'Brien. —The whole is a level hearth of some width, from 6 to 8 feet square, at the corner of which is the fire-place, from 24 to 30 inches square, and from 12 to 18, often 20, inches deep. Inside it is lined with cast iron plates, the bottom plate being from 2 to 3 inches thick. Figure 293 represents a cross section through the fire-place and reverberatory, commonly called the iron of rever-

presents the fire-place, which, as remarked above, is of various dimensions. The inners *b* is from 7 to 8 inches above the bottom, and more or less in width ac-

subject to the same instances. The blast is produced by wooden bellows of the common form, or more generally by square wooden cylinders, urged by water wheels. The ore is chiefly reduced in the crystalline magnesian. This ore very readily falls in a regular scale, and when roasted varies from the size of a pea to the size of a grain. Sometimes the ore is employed without roasting. In the working of such ores much depends on the skill and experience of the workman. The result is subject to considerable variation, that is, whether economy of coal or that of ore is our object. Thus a modification is required in the construction either of the whole apparatus or its parts only. The temperature varies in many respects. One workman by looking by the eye into the hearth, observes some of the expense of obtaining a good yield. Another by carrying the iron more laboriously at the common furnace, obtains a larger amount of iron, though at the sacrifice of coal. Good workmen pay great attention to the tuyere, and alter its dip according to the state of the operation. The general arrangement is as follows:—The hearth is lined with a good coating of charcoal dust; and the fire plate, or the plate opposite the blast, is lined with coarse ore, inasmuch as it is at our disposal. If no coarse ore is employed, the hearth is lined with coal, and the small ore piled against a disk of coal dust opposite the tuyere. The blast is at first urged gently, and directed upon the ore, while the coal at the tuyere is kept cool. Four hundred pounds of ore are the common charge, two-thirds of which are then smelted, and the remaining third, generally the finest ore, is held to reserve, to be thrown on the charcoal when the fire becomes too brisk. The charcoal is piled to the height of two, sometimes even three and four feet, according to the amount of ore to be smelted. When the blast has been applied for an hour and a half, or two hours more of the iron is melted, and forms a pasty mass at the bottom of the hearth. The blast tuyere may be urged more strongly, and if any pasty or spotty mass yet remains, it may be brought within the range of the blast and melted down. In a short time the iron is reduced, and the scoriae are permitted to flow through the tapping hole, so that but a small quantity of scoria remains at the bottom. By turning the iron bars, the lump of pig iron is brought before the tuyere. If the iron is too pasty to be lifted, the tuyere is made to dip into the hearth; in this way the iron is raised from the bottom, directly before, or to a point above the tuyere, until it is worked into a coherent ball, twelve or fifteen inches in diameter. This ball is brought to the hammer or squeezer, and shingled into a bloom, which is either cut in pieces to be stretched by a hammer, or sent to the rolling mill to be formed into malleable bar iron. A mixture of fibrous iron, cast iron, and steel, is the result of the above process; the quality of the iron depends entirely on the quality of the ore, for there are no opportunities for the exercise of any skill to create improvement in the process; poor ore cannot be smelted at all. In Vermont, where the rich ungotten ores are smelted, a ton of pig iron costs about 4 dollars; 4 tons of ore, and 300 bushels of charcoal are required to produce 1 ton of bloom. The *Furnace à la Française*, or *Stück-ofen* of the Germans, holds a place intermediate between the *Common hearth* and the high blast furnace now in general use. The iron produced in the kind of furnace is generally of a very superior kind, but it is very laborious at the present time, on account of the great expense of its manipulation. The *Stück-ofen*, or *Alexander furnace*, as it is sometimes called, is a small cupola, its interior having the form of a double crucible. It is usually from 10 to 16 feet high, and 24 inches wide at bottom and top, and measures at its widest part about 8 feet. There are generally two tuyeres, both on the same side; the breast is open, but during the smelting operation it is shut by bricks. The furnace is heated previous to closing in the breast; after which charcoal and ore are thrown in; the blast is then

turned on, as soon as the ore passes the tower, iron is deposited at the bottom of the hearth, while the under part of the tower is filled to escape through a hole in the dam; the tower is generally kept low upon the surface of the melted iron, which thus becomes widened, as the iron runs the tower is raised. In about 24 hours one ton of iron is deposited at the bottom of the furnace; the blast is

turned off, and the iron, which is in a solid mass, is then lifted by a crane, or a derrick, as the Germans call it, is lifted from the furnace by a pair of strong ropes, which are fastened at their upper end to a strong crane, and then lowered to a furnace, where it is heated by a gas furnace, and then turned into a ladle, and then poured into a mould, and finally converted into bars by a pair of rollers. Much of the furnace is charged with coke and coal, and the iron is removed. The process, as well as that of the Catalan hearth, is improved, and the iron contains more than 4 per cent of iron.

The general form of the modern (harpy) blast furnace, as used in the United States, where this fuel is the most common, is shown in the section, and is similar to that of the Catalan hearth, whether any other furnace are in the present state of operation in that country, is shown in section in the 994 and is similar to that of the Catalan hearth. The iron is drawn off by a pair of rollers, and is drawn off by a pair of rollers, and is drawn off by a pair of rollers. The height is 35 feet; hearth from base to the bushes, 5 feet, 6 inches; width at the bottom, 24 inches; and at top, 36 inches. The towers are 20 inches above the base. The bushes are 9 feet 6 inches in diameter, and measure from the top of the crucible 4 feet, which gives about 60° slope. The blast is conducted through a short iron or cast-iron pipe, and below the bottom stone, but the tower. The top is furnished with a chimney, by which the blast from the tower is drawn off. Around the top is a fence of iron or wood.

Fig. 996 shows the method of preparing and arranging the hearth stones. *d* is the bottom stone, made of a fine close-grained sandstone, from 12 to 15 inches thick, at least 4 feet wide, and 6 feet long, it reaches underneath that half of the dam-stone *b*. The bottom stone is well bedded in

fire-clay, mixed with three-fourths sand. After the bottom stone is placed, the upper part of which must be three-fourths of an inch lower at the dam stone than at the

back, the two side stones, are laid on a bed of fire-bricks. These stones must be at least 4 feet and a half long, reaching from the back to the front of the furnace. They

must be made sufficiently heavy to be a proof of their strength; the transverse section of the grain must be in all cases parallel to the fire, the side stones are sometimes square, but always beveled according to the slope of the hearth. They must exceed the top stone in area and weight; the latter must be the best, and therefore of the best of the local quality. They should be from 24 to 24 inches square, or even larger; the top stone has, at the end of the arch, are cut at least the same are built. These stones are not much further than the front of the furnace, and are therefore scarcely four feet long; the top stone, however, is generally sufficiently high to reach at once the crucible in its 3rd and 4th. After the stones are fixed, the back stone is put in, and then the transverse side stones, between the transverse and the rough wall of the furnace, which is filled and walled up with common brick or stone.

In starting a charcoal furnace, it is first the only done by turning a fire for several weeks in the interior, which has a temporary roof of bricks. The lower part of the furnace or the hearth is then filled gradually with charcoal, and when the fuel is well settled, and the furnace half filled, ore may be charged in; it is common advice to increase the draught by forming grates by laying across the top a strong iron bar, as high up as the dam-stone, by resting upon this bar a row of iron bars or risers, and by pushing their points against the back stone of the hearth. There is not much to be made during the first 24 hours; most of the ore is transferred to the blast, and the iron which comes down gets cold on the bottom stone, where it is retained; the blast should not be urged too fast at first, but increased gradually, in order to avoid the serious evil arising from a cold hearth; if all goes well the hearth will be free from cold iron or clinkers in a week, the yield of iron will increase, and the fusion may be increased likewise. The average charge of charcoal, which should be dry, coarse, and hard, is about 15 bushels. According to Overman's experience, the most favourable height for a charcoal furnace is 5 or 6 feet; if lower this standard they consume too much fuel, if above they are troublesome to work; if it be desired to enlarge the capacity of a furnace, he thinks it better to increase the diameter of the lozenges, or to curve the vertical section. There is much difference of opinion among the makers of furnaces in the subject of the proper size for the throat of the furnace; the tendency of narrow throats would seem to be to consume more coal than wide ones; but in Pennsylvania and throughout the whole west, where narrow ones are preferred, the consumption of charcoal per ton of iron is from 160 to 180 bushels, while in the state of New York, and further east, where the furnace throats are wider, the consumption is from 120 to 130 bushels. Another subject which demands the most careful attention is the regulation of the blast. A weak charcoal will not bear a much greater pressure than from half a pound to five-eighths of a pound to the square inch; strong coarse charcoal will bear from three quarters of a pound to a pound; and again, it may be laid down as a rule that the larger the throat in proportion to the lozenges, the stronger ought to be the blast, and that a narrow top and wide lozenges, which they permit a weaker blast, involve the loss of much fuel. In every case a careful regulation of the ores at charcoal furnaces will prove advantageous; this is the most careful of saving coal and blast, and of avoiding many annoyances in the working of the furnace.

With regard to hot blast, as applied to charcoal furnaces, Overman remarks, that under some circumstances it might be advantageous, but in others it is decidedly injurious; that it is, at least, a questionable improvement, and it may be doubted whether the manufacture of bar iron has derived any benefit from it; quaker-iron, it has not. Hot blast is quite a help to imperfect workmen: it melts refractory ores, and delivers good foundry metal with facility.

English process of iron making. — Mr. Hunt, in his very valuable "Mineral Statistics," gives us the total quantity of pig iron produced in Great Britain in the year 1855: — 3,456,064 tons, as follows. —

	Tons.
Northumberland	4,323
Derbyshire	1,001,104
Yorkshire, North Riding	152,370
" West Riding	63,000
Leicestershire	135,217
Lincolnshire	8,701
Gloucestershire	10,204
North Staffordshire	143,816
South Staffordshire and Worcestershire	147,200
Guernsey	11,000
Northamptonshire	8,780
Warrington and Lancaster	2,040
North Wales	18,136
South Wales	603,478
Scotland	182,200

3,478,000

The number of furnaces in blast to furnish this amount of work are, in England, 322, distributed over 134 iron works; in Wales, 153, distributed over 47 works; and in Scotland, 133, over 34. To supply these furnaces there were raised 4,343,000 tons of ore, the estimated value of which, at a mean of 11s. per ton, was £478,220; that of the pig iron, at a mean price value of 31s. a ton, being 14,024,160. Of the amount of iron, 1,000 tons were agricultural cast-iron from the coal measures of North Staffordshire and Worcestershire; nearly 1,000,000 tons from the coal measures of North and South Wales; and 2,317,000 tons agricultural cast-iron from Scotland. The annual production of pig iron over the whole world was estimated by Mr. Mackintosh in December, 1853, as follows:—

	Tons.
Great Britain	3,000,000
France	700,000
United States, &c.	700,000
Prussia	200,000
Austria	200,000
Belgium	200,000
Russia	100,000
Sweden	100,000
Various German States	100,000
Other countries	200,000

6,000,000

From which it appears that the quantity of iron made annually in this island alone, is nearly, if not quite, as large as the total quantities produced in all other countries. The nature of the ore which forms the staple supply of the English furnaces (argillaceous carbonate), and the universal adoption of coke and coal as fuel, have led by necessity to a method of manufacture of iron quite peculiar to this country, and wholly inapplicable to those external elements that are carried on by means of charcoal. We shall proceed to describe the various steps of this manufacture in detail:—and first,

Of the blast furnace.—The blast furnaces at present in use are of various sizes, being from 35 to 60 feet in height, and at the *hoops*, or widest part, from 12 to 17 feet. The internal form commonly adopted consists essentially of two frustums of cones meeting each other at their bases, at the point where the widest part or the top of the *hoops* is situated. From this point the furnaces gradually contract both upwards to its mouth, and downwards to the level of the tuyeres below. The hearth, properly speaking,

is that part of the furnace only which receives the flux of metal and cinder, as they fall below the level of the tuyeres. It forms a short prolongation from that point of the lower inverted cone. From the lower upward the width gradually decreases to the *top* or head, which varies from 7 to 9 feet in diameter, according to the size of the furnace. The hearth is generally a cone, from 2½ to 3 feet square. The air is introduced by one, two, or three small apertures, called *registers*.

When two tubes are used, the diameter of each blow-pipe is about three inches in diameter, and the pressure of the blast is from 24 to 30 lbs. on the square inch. To prevent the tubes from being cooled by the intense heat to which they are ex-

posed, a stream of cold water is caused constantly to flow round their vessels by an arrangement which will be immediately understood by an inspection of fig. 987, which represents a section of a tuyere near the vent, showing the cold water entering the space by the tube *a*, and the hot water running off by the tube *b*. The upper part of the furnace above the boches is called the *throat* or *body*. It is formed by an interior lining of fire-bricks, about 14 inches in thickness, between which and the exterior masonry is a lining of less refractory and comparatively porous air-bricks, to act as a screen of aqueous vapour. In the base of the furnace four arches are left, the back and sides are called *tympanums*, the front is called the *crucible* or *front*; the bottom of the furnace is formed either of large

blocks of coarse ash or of large fire-bricks. The materials are charged into the furnace through the tassel head, which is provided with one or more apertures for the purpose. The general form of a blast furnace is shown in fig. 986, and the following measurements represent the interior structure of two that worked well. —

	No. 1.	No. 2.
Height from the hearth to the throat or mouth	45	69
Height of the crucible or hearth	8	6
" of the boches	30	12
" of the cone	8	12
" of the chimney or mouth	2	2
Width of the bottom of the hearth*	3	2
" at its upper end	12	17
" of the boches†	12	11
" at one-third of the belly	6	9
" at two-thirds of ditto	4	5
" at mouth	5	5
Inclination of the boches‡	55	53

Fig. 989 represents the hearth and boches in a vertical side section. *a* is the *tympanum* stone, and *b* the *tympanum* plate, for confining the liquid metal in the hearth. The latter is wedged firmly into the side walls of the hearth; *c* is the dam-stone, which occupies the whole breadth of the bottom of the hearth, excepting about six inches, which space, when the furnace is at work, is filled before every cast with a strong binding sand. This stone is fixed in place by a cast-iron plate *d*, called the *dam plate*, of considerable thickness and proper shape. The top of the dam-stone, or rather the notch of the dam-plate, lies from 4 to 8 inches under the level of the tuyere hole. The space under the tympanum plate, for 5 or 6 inches down, is rammed full for every cast with a strong loamy earth or even fine clay, a process called *tympanum stopping*.

* The width of the hearth varies greatly in the furnaces in different localities. In Scotland it varies from 6 to 8 feet; in the Welsh furnaces from 8 to 10 feet. When coke is used as fuel Mr. Trueman thinks 6 feet a sufficient width for all purposes; but with coal, with inclined furnaces, 16 to 19 feet across the boches, he thinks a 7 feet hearth to be more advantageous.

† The diameter of the boches in some of the Welsh furnaces is as much as from 14 to 16 feet.

‡ The angle with which the boches rise in different furnaces varies from 50° to 60°. Mr. Trueman thinks that when the full smelting power of the furnace is desired, the angle should not be less than 70°, which is about that of the Dutch furnaces.

The blowing machine employed in Scotland is generally run over by steam, in which a screw is fixed at each end of the cylinder, and made in the same way. The valves are top and bottom, and the cylinder is half covered with valves, which open and close when the vacuum is made with the cylinder, and afterwards shut by their own weight. A piston rod, with the piston, goes at each end exposed to the steam, both in the ascent and descent, whence these blowing machines always double stroke.

959

The pressure of the air is made to vary through a very considerable range, according to the nature of the fuel, and the season of the year; for as to ensure the atmosphere is well saturated it must be heated with a compensating force. The heat is from 11 to 15 pounds on the scale, the average in Scotland being 13 lbs. The pressure is kept even through which the air flows, also vary with the nature of the fuel and the air.

In a large apparatus employed at the Cyfarthfa works, moved by a full horse steam power, the piston rod of the blowing cylinder is connected by a parallel motion mechanism with the opposite end of the working beam of the steam engine. The cylinder is 9 feet 4 inches diameter, and 11 feet 4 inches high. The piston has a stroke 8 feet long, and it rises 13 times in the minute. By calculation the area of the space passed by the piston is a minute, and supposing that the volume of the air expanded is equal to only 10 per cent. of that area, we find that 14,000 cubic feet of air are expelled every minute. Hence a horse power applied to blowing machinery of this nature gives an average of 17 cubic feet of air per minute.

At the establishment of Cyfarthfa for blowing iron and making furnace and the other corresponding works, three steam engines are employed, one of 100 horse power, another of 80, and a third of 10, which constitute on the whole a force of 190 horses, or 24 horses and 1/4 per furnace, supplying the fires to consume one-fifth of the blast. In the whole of the works of Messrs. Crawshaw, the proprietors of Cyfarthfa, the power of about 140 horses is expended in blowing 12 cooling furnaces and their satellite fires, which give from 2 to 2 1/2 lbs. of air per cubic foot of air per minute for the finest. Each of the furnace measures about 3.507 cubic feet of air per minute.

The form of the blast furnace from the boilers to the throat is explained in fig. 959 as a truncated cone, and such was formerly in variably the construction; but years have however considerable variations have been introduced. In Scotland the body of the furnace frequently is carried up cylindrical, or nearly so, for a considerable height, terminating with the usual truncated cone to the mouth; in other places a curved line is substituted for a straight one. The form adopted in some furnaces recently erected at Fife and Blair is shown in fig. 1000.

The diameter of the throat or filling place is a subject of very great importance to the operation of the furnace. Mr. Ironmasters are, we believe, agreed as to the propriety of the narrow top formerly adopted; the waste of fuel in such furnaces, where the width of the throat scarcely exceeds one-fourth of the diameter of the furnace, was very great, the average yield of coal to the ton of crude iron exceeding 8 tons; by enlarging the throat to one-third, the consumption of coal was reduced to 4 tons, and by enlarging the throat to one-half it was reduced to 2 tons. Mr. Trautman states that on reducing the diameter of the throat of a furnace at Glasgow from 9 feet to 6, the make of pig iron weekly fell off from 97 tons, to an irregular make of from 50 to 70 tons; and that while with the 9 feet throat the consumption of coal was 45 cwts. to the ton of iron, it rose with the 6 feet throat to 75 and 90 cwts., the quality of the iron being exceedingly bad. On enlarging the throat to 9 feet, the make, for a period of 6 months, averaged over 100 tons, with a good yield of coal and other materials. Mr. Trautman appears to question the utility of reducing the diameter of the furnace at the top, which was only adopted in the first place from an erroneous impression that the furnace could be filled best through a contracted mouth; but it may be questioned whether this widening of the throat may not be carried too far, so as to disperse the heated gases too rapidly, and whether a diameter much greater than one-half of the largest diameters of the furnace above the boilers can with safety be adopted. On this subject Mr. Kenyon Blackwell says, "If that part of the blast

furnace communicating at the point where it attains its greatest width were continued of the same wide dimensions upwards to its mouth, two objectionable results would ensue:

first the upper part of the furnace would be cooled by the too rapid dispersion of the

ascending column of heated gases; and by the entire absence of the reverberating effect of the contracted mouth; and secondly, the materials could not be equally spread over the firing holes over so wide a surface. The diameter of the upper part furnace ought, therefore, to be such as will cause the materials thrown in at the firing holes to distribute themselves equally in their descent over every part of the internal area of the furnace, and will produce such a reverberation only of heat as shall be sufficient to expel the water and carbonic acid contained in the materials, without consuming any of the carbon of the fuel, which ought to remain intact until it reaches the lower regions of the furnace, where it is required as carbonic oxide, and produces the reactions on which the reduction of the ore depends."

Calcination of the ironstone.—

This is effected either in kilns, or in the open air; the object being to separate carbonic acid, water, sulphur, and other substances volatile, at a red heat. The operation is performed most effectually, and probably at the smallest cost, in kilns. The interior shape of the calcining kilns differs in different works, but they may all be reduced to that of the common *lump* kiln. A coal fire is first lighted at the bottom of the kiln, and the ironstone is placed over and around, until the floor is covered with red hot ore; a fresh layer of ironstone, with about 3 per cent. of coal, is then laid on, to the depth of 6 or 9 inches; and when this is red hot, a second layer is added, and so on gradually till the kiln is filled; by the time this is done, the lowermost layer is cold and fit to draw, so that the working of the kiln is a continuous operation. When the ore is calcined in the open air, a heap mingled with small coal (if necessary), is piled up over a stratum of larger pieces of coal, the heap being 3 or 6 feet high, by 15 or 20 broad. The fire is applied at the windward end, and after it has burnt a cer-

1001

the way, the heap is piled up at the sides externally, so far as the nature of the ground, or the convenience of work requires. From the impossibility of regulating the draught, and from exposure to the weather, the combustion of coals is not so well suited to the open air as in kilns; and as to the nature and cost of the two methods, Mr. Truran estimates that the quantity of coal per ton of iron in the kiln, the standard-weight of metal, and the open air, two hundred weight of metal, and a half hundred-weight of iron; and that while the cost of smelting the kiln is barely a penny per ton, that of smelting the heaps in the open air runs at from one and a half pence to two pence per ton, during the period they are under fire, amounts to fifty pence per ton. Against this must, however, be placed the cost of smelting the kiln, which according to the same author's estimate, for a kiln of a capacity equal to 70 tons of pig-iron, and which will produce 100 tons weekly, is £100. The cost of the fuel is estimated at 10 per cent. of the weight; it has undergone a considerable change by the operation, it is the raw coal, it is grey or black, heavy, and of a strong cohesion, perfracted by the impact, after passing in it but a very few, and even nearly to the tongue, is cracked in all directions, so of a light texture, porous throughout, and very powerful in the furnace. It should be carried to the furnace at once at present, or if it should be carried from the raw coal.

Fuel.—The only fuel that is used in the blast furnace is iron ore, which is the most valuable as it comes from the quarry, or is mined at that, by which it is deprived of water and sulphur. The lowest end of the coal furnace usually remains in the furnace, and to the coal furnace itself are fed all the iron and the coal, and the fuel is fed at the bottom of the furnace, which is the best of refractory materials necessary for smelting these parts of an iron furnace that are required to contain the intense extremity of heat, as well as the means of refractory clay, if which the bricks are made, with which the middle and upper parts of the furnace are lined. "Too many objections to this favoured island may be pointed out, in which all the abundant materials occur almost on the same spot; but when to this is joined the convenience of water carriage, as happens in many places, that some may object to be of an obnoxious underpinning and a dearish temper is when the whole arrangement and prodigal beneficence of nature fails to produce corresponding results."

The composition of the limestone to be used in smelting operations is of considerable importance; where coal or iron ore are used, the presence of silica and in the limestone is not autogenous; if clay ores are the main material from which iron is manufactured, a magnesian limestone is preferable, but an aluminous limestone should be used where silica is not produced. Chemical analysis is a necessary step in the selection of which class a particular limestone belongs, as there is often much in the external appearance by which a pure limestone may be distinguished from one containing 10 or 50 per cent. of foreign matter.

Carbonised pit-coal or coke was, till within the last twenty-five years, the sole combustible used in the blast furnace. Coal is coked either in the open air or in kilns. In the former, as practised in Staffordshire, the coal is distributed in circular heaps about 5 feet in diameter by 4 feet high, and the middle is occupied by a low brick chimney piled with loose bricks, to open or to leave interstices between them, especially near the ground. The larger lumps of coal are arranged round the chimney, and the smaller ones towards the circumference of the mass. When everything is adjusted a kindling of coals is introduced into the bottom of the brick chimney, and, to render the combustion slow, the whole is covered with a coat of coal slum, the chimney being loosely covered with a slab of any kind. Openings are occasionally made in the crust, and afterwards shut up, to quicken and retard the ignition at pleasure during its continuance of twenty-four hours. Whenever the carbonisation has reached the proper point for forming good coke, the covering of coal slum is removed, and water is thrown on the heap to extinguish the combustion, a circumstance deemed useful to the quality of the coke. In this operation in Staffordshire coal loses the half of its weight, or two tons of coal produce one of coke.

In order to prepare larger quantities of coke at once, long ridges are often substituted for circular heaps, the length of which varies with circumstances and the consumption of coke; they sometimes extend to the length of 200 feet. On erecting one of these ridges a string is stretched along the coking station, in the direction of which large pieces of coal are placed slanting against each other, leaving a triangular space between them, so that a longitudinal channel (gutter or passage) is formed through which the string passes. In arranging the pieces it is necessary to pay attention to the natural stratification of the coals, which should be at right angles to the longitudinal direction of the ridge. Parallel with the first series of coals is placed a second, and

there a third, and so on; but the pieces constantly diminish in size until the whole measures 6 feet in height. From the bottom of the heap is then made, without particular care to the arrangement, the largest piece below and the smallest above, until it has reached a height of about 3 feet. To increase the heat, sticks of charcoal are placed, of 2 feet from each side, projecting above throughout the whole length of the ridge, which, when subsequently removed, leave vacant spaces for the introduction of burning coal. The ridge, being thus filled at once from 100 feet to 200 yards in length and 100 yards in width. As soon as the lower strata of the stack wastes and flows down at any one part, and a burning of soft coals has commenced, the ridge is frequently topped the progress of the fire by means of a small pointed coal door, regulating the operation until the whole ridge is consumed, when it is left two or three days to cool; the covering on the side exposed to the wind is removed to clear and covered in stormy weather. When the fire is nearly extinguished, which occurs in two or three days, the ridge is drawn. The ridge of stack is small, but not very economical. The fire proceeds from the upper part of the ridge in a downward direction, twice is the lower and superior parts, sometimes the coal in the upper strata takes fire before that in the inferior has acquired the proper quantity necessary for charring, and is still in want of a supply of air, which cannot be furnished from within, and must not be excluded by a covering. During the time, therefore, that the lower part of the heap are being converted into coke, the upper part is being rapidly, though unavoidably, consumed. For further details respecting working see the articles Coal and Coals.

"The following is" of a coal blast furnace is an operation which requires much skill and experience. A fire of wood is first lighted on the hearth, upon this is placed a quantity of coke, and when the whole is well kindled, the furnace is filled to the throat with regular charges of calcined ore, limestone, and coke, and the blast, which should at first be moderate, is turned on. At the works around Merthyr Tydfil, the first charges generally consist of 3 cwts. of calcined argillaceous ore, and 1½ cwt. limestone, to 4 cwts. of rich coke; this burden is kept on for about 10 days, it is then increased to 6 cwts. of calcined ore and 2½ cwt. of limestone (Truran). The cinders usually make their appearance in about 12 hours after the blowing, the metal flows in about 10 hours after, collecting in the hearth to the extent of four or five tons in 24 hours after blowing. If all goes on well about 22 tons of metal will be produced in the first week, 34 tons in the second, 55 in the third, and 70 tons in the fourth; after 10 or 12 weeks the produce will average 110 tons. By blowing the furnace in its infancy a much greater produce of iron may be obtained, than by the ordinary of its subsequent working. Mr. Truran relates the following case in point. A furnace was blown in at the Abercromby works with such volumes of blast and rich burden of materials that a cast of 20 tons was obtained within 14 hours after applying blast. The first week's blowing produced 260 tons, at which rate it continued for two or three weeks, when it rapidly diminished, falling as low as 10 tons for one week's make. From this deplorable state it was made to produce 26 tons, and, after considerable delay, 110 tons; but with a large increase in the yield of materials over that at the other furnaces. When a furnace is first blown in it should be made to produce grey iron; but the tendency of forcing is to produce a white iron with a dark smothering cinder.

The quantity of air thrown into a blast furnace in full work is enormous, exceeding in weight the bulk of all the soiled materials used in smelting. A furnace working on ordinary iron of a capacity of 275 yards receives 3390 cubic feet of air per minute, which amounts weekly to 169½ tons; when working on white iron a larger volume of blast is employed, averaging 7870 cubic feet per minute, or 2315 tons per week.

The disorders to which blast furnaces are liable have a tendency to produce white cast iron. The colour of the slag or scoria is the surest test of these derangements, as it indicates the quality of the produce. If the furnace is yielding an iron proper for casting into malleable the slag has a greenish verification and is slightly translucent. When the dose of lime increased the slag becomes opaque, dull, and of a greenish yellow tint, with blue crystallized scales. Lastly, when the furnace is producing white metal, the slag are more or less black and glassy. The scoria from a coke are much more loaded with lime than those from a charcoal blast furnace. This excess of lime appears adapted to absorb and carry off the sulphur which would otherwise injure the quality of the iron. From numerous analyses we have made of blast furnace cinders we select the following as illustrating their general composition under different conditions of the furnace.

which much soluble sulphate of iron is removed. Unfortunately, the process of calcination does not remove any of the phosphoric acid, which enters a judicious complement of the cinders in the blast furnace. We have repeatedly submitted "forge cinders" to analysis, and give in the following table the average results of our experiments.

Analyses of Forge Cinders. (DR. NOAD.)

I. Yr. cinder from rolled metal. II. Top cinder from pig-iron furnace. III. Cinder from rolled metal. IV. Mixed cinder from the heap above a new blast furnace. V. Cinder from the heap above the furnace during the process of slinging. VI. Specimen from a large heap of cinders, by the side of the furnace.

Hot blast — One of the greatest improvements ever made by simple means in any manufacture, is the employment of hot air instead of the ordinary blast of the atmosphere, in supplying the blast of furnaces for smelting and fusing iron. The discovery of the superior power of a hot over a cold blast in fusing refractory lumps of cast iron, was accidentally observed by Mr. James Beaumont Neilson, engineer to the Glasgow Gas Works, about the year 1827, at a smith's forge in that city, and it was made the subject of a patent in the month of September in the following year. No particular construction of apparatus was described by the inventor by which the air was to be heated, and conveyed to the furnace; but it was merely stated that the air may be heated in a chamber or closed vessel, having a fire under it, or in a vessel connected in any convenient manner with the forge or furnace. From this vessel the air is to be forced by means of a bellows into the furnace. The quantity of surface which a heating furnace is required to have for a forge, is about 1,260 cubic feet; for a cupola furnace, about 10,000 cubic inches. The vessel may be enclosed in brickwork, or fixed in any other manner that may be found desirable, the application of heated air in any way to furnaces or forges, for the purposes of working iron, being the subject claimed as constituting the invention.

Wherever a forced stream of air is employed for combustion, the resulting temperature must evidently be impaired by the coldness of the air injected upon the fuel. The heat developed in combustion is distributed to three portions; one is communicated to the remaining fuel; another is communicated to the atmosphere and to the volatile products of combustion; and a third to the iron and fluxes, or other surrounding matter, to be afterwards dissipated by wider diffusion. This inevitable distribution takes place in such a way, that there is a nearly equal temperature over the whole extent of a fire-place, in which an equal degree of combustion exists.

We thus perceive that if the air and the coal be very cold, the portions of heat absorbed by them might be very considerable, and sufficient to prevent the resulting temperature from rising to a proper pitch; but if they were very hot they would absorb less caloric, and would leave more to elevate the common temperature. Let us suppose two furnaces charged with burning fuel, into one of which cold air is blown, and into the other hot air, in the same quantity. In the same time, nearly equal quantities of fuel will be consumed with a nearly equal production of heat; but notwithstanding this, there will not be the same degree of heat in the two furnaces, for the one which receives the hot air will be hotter by all the excess of heat in its air above that of the other, since the former air adds to the heat while the latter abstracts from it. Nor are we to imagine that by injecting a little more cold air into the one furnace, we can raise its temperature to that of the other. With more air indeed we should burn more coals in the same time, and we should produce a greater quantity of heat, but this heat being diffused proportionally among more considerable masses of matter, would not produce a greater temperature; we should have a larger space heated, but not a greater intensity of heat in the same space.

Thus, according to the physical principles of the production and distribution of heat, fires fed with hot air should, with the same fuel, rise to a higher pitch of tem-

perature than fires fed with common cold air. This consequence is independent of the masses, being as true for a small stove which burns only an ounce of charcoal in a minute, as for a furnace which burns a hundred-weight; but the excess of temperature produced by hot air cannot be the same in small fires as in great, because the waste of heat is usually less the more fuel is burned.

This principle may be rendered still more evident by a numerical illustration. Let us take, for example, a blast furnace, into which 600 cubic feet of air are blown per minute; suppose it to contain no ore but merely coal or coke, and that it has been burning long enough to have arrived at the equilibrium of temperature, and let us see what excess of temperature it would have if blown with air of 300°C . (572°F .), instead of being blown with air at 0°C .

600 cubic feet of air, under the mean temperature and pressure, weigh a little more than 45 pounds avoirdupois; they contain 10½ pounds of oxygen, which would burn very nearly 4 pounds of carbon, and disengage 16,000 times as much heat as would raise by one degree per cent. the temperature of two pounds of water. These 16,000 portions of heat, produced every minute, will replace 16,000 other portions of heat, dissipated by the sides of the furnace, and employed in heating the gases which escape from its mouth. This must take place in order to establish the assumed equilibrium of caloric.

1002

If the 45 pounds of air be heated beforehand up to 300°C ., they will contain about the eighth part of the heat of the 16,000 disengaged by the combustion, and there will be therefore in the same space one-eighth of heat more, which

will be ready to operate upon any bodies within its range, and to heat them one-eighth more. Thus the blast of 300° C. gives a temperature which is nine-eighths of the blast at zero C., or at even the ordinary atmospheric temperature; and as we may reckon at from $2,300^{\circ}$ to $2,700^{\circ}$ F. (from $1,200^{\circ}$ to $1,500^{\circ}$ C.), the temperature of blast furnaces worked in the common way, we perceive that the hot-air blast produces an increase of temperature equal to from 270° to 360° F.

Now in order to appreciate the immense effects which this excess of temperature may produce in metallurgic operations, we must consider that often only a few degrees more temperature are required to modify the state of a fusible body, or to determine the play of affinities dominant at lower degrees of heat. Water is solid at 1° under 32° F.; it is liquid at 1° above. Every fusible body has a determinate melting point, a very few degrees above which it is quite fluid, though it may

be partly below it. The same observation applies to ordinary chemical affinities. Charcoal, for example, which reduces the greater part of metallic oxides, begins to do so only at a determinate pitch of temperature, under which it is inoperative, but a

few degrees above, it is in general lively and complete. It is unnecessary in this article to enter into any more details, to show the balance of a few degrees of heat more or less in a furnace upon chemical operations, or merely upon physical changes of state.

FIG. 1002, 1003, exhibit the apparatus of the hot blast as mounted at the Finner Park works, belonging to William Jessop, Esq., in every respect to detail. The drawings from which the wood cuts are minutely copied were kindly furnished for this work by Mr. Joseph Glyn, F.R.S., the distinguished engineer of the Railway Iron Works.

The resulting furnaces have now generally three systems, and three sets of air heating furnaces. The figures show two sets heat together; the third set being attached on account of peculiar local circumstances. The air enters the horizontal pipe A, in the ground plan, *see* 1002, on one side of the arched or siphon pipes, shown in upright section in *see* 1003, and passes through three pipes to the horizontal pipe B, on the other side, whence it proceeds to the blast furnace. These siphon pipes are flattened laterally, their section being a parabola, to give more heating surface, and also more depth of pipe (in the vertical plane), so as to make it stronger, and less liable to bend by its own weight, when softened by the red heat. This system of arched pipe apparatus is set in a kind of oven, from which the flue is taken out at the top of it, but it there again descends, before it reaches the chimney, entering it nearly at the level of the fire grate, (as with coal gas retorts). By this arrangement, the pipes are kept in a bath of ignited air, and not exposed to the corroding influence of a current of flame. The places and directions of these oven flues are plainly marked in the drawing.

Fig. 1001 is a plan of the blast furnace, drawn to a smaller scale than that of the preceding figures.

The three sets of hot-blast apparatus all communicate with one line of conducting

pipes, A, which leads to the furnace. Thus in case of repairs being required in one set, the other two may be kept in full activity, capable of supplying abundance of hot air to the blast, though of a somewhat lower temperature. See SMELTING for constructions of different blast furnaces; also PUDLING.

During a visit which Dr. Hve made to Mr. Jessop, at Buxton, he found this eminent and very ingenious iron-master had made several improvements upon his hot-blast arrangements, whereby he prevented the alteration of form to which the angled pipes were subject at a high temperature, as also that he was about to employ five tuyères instead of three. For a drawing and explanation of his furnace-feeding apparatus, see SMELTING.

The experiments through which Mr. Nielson's important discovery was introduced into the iron manufacture, were made at the Clyde Iron Works, where the fuel generally made use of was coke, derived from splint coal; during its conversion into coke, this coal sustained a loss of 33 per cent. During the first six months of the year 1830, when all the cast iron in the Clyde Iron Works was made by means of the cold blast, a single ton of cast iron required for fuel to reduce it 8 tons $1\frac{1}{2}$ cwt. of coal, converted into coke. During the first six months of the following year, while the air was heated to near 300° F., 1 ton of cast iron required 5 tons $3\frac{1}{2}$ cwt. of coal converted into coke. The saving amounts to 3 tons 18 cwt. per ton of iron, from which must be deducted the coal used in heating the air, which was nearly 9 cwt. This great success induced the Scotch iron-masters to try a higher temperature, and to substitute coke for coal; and during the first six months of the year 1833, the blast being heated to 600° F., 1 ton of cast iron was made with 2 tons $5\frac{1}{2}$ cwt. of coal. Add to this 8 cwt. of coal for heating, and we have 2 tons 13 $\frac{1}{2}$ cwt. of coal to make one ton of iron. An extraordinary impetus was given by this discovery to the iron manufacture in Scotland, where, from the peculiar nature of the coal, and from the circumstance that, with a heated blast, Mather's blackband ironstone could be exclusively used, its importance was more highly felt than in England and Wales. According to Mr. Finch's statement (Sirivenor's "History of the Iron Trade"), there were in 1830 only eight works in operation in Scotland, which made in that year 37,500 tons of pig iron; in 1838 there were eleven works, consisting of 41 furnaces, which made 147,500 tons, being an increase in eight years of 110,000 tons per annum; in 1839 there were 50 furnaces in blast, making 195,000 tons; in 1851, 750,000 tons of pig iron were made; and in 1856, with 137 furnaces in blast, the make rose to 860,500 tons. The influence of hot blast has likewise been felt in the anthracite district of South Wales, where that coal is now successfully used, and where several new furnaces have in consequence been erected. In short, notwithstanding the opposition with which the introduction of hot blast was met by engineers, as being destructive of the quality of the iron, so great have been the advantages derived from it, that at the present time more than nineteen-twentieths of the entire produce of the kingdom is made in furnaces blown with heated air.

Mr. Truran, in his recent work on the iron manufacture of Great Britain, gives it as his opinion that the effects of hot blast have been greatly exaggerated, and that it is to improvements in the preparation of fuel and ore in the furnaces, in blowing engines, and in the smelting process, far more than to the heating of the blast, that we must refer the great reduction in the yields of coal in recent times; he thinks that the comparatively large produce which has been obtained from the Scotch furnaces, is to be referred to the general use of carbonaceous ore, which melts at a low temperature; and which, from its comparative freedom from earthy matters, requires but a minimum dose of limestone for fluxing. Against this opinion of an English writer on iron smelting we may place that recorded by an American metallurgist, Mr. Overman, who has written a large and in many respects a valuable treatise on the manufacture of iron, as conducted in America. "The economical advantages arising from the application of hot blast, casting aside those cases in which cold blast will not work at all, are immense. The amount of fuel saved in anthracite and coke furnaces varies from 30 to 60 per cent. In addition to this, hot blast enables us to obtain nearly twice the quantity of iron within a given time that we should realise by cold blast. These advantages are far more striking with respect to anthracite coal than in relation to coke or to bituminous coal. By using hard charcoal, we can save 20 per cent. of fuel, and augment the product 50 per cent. From soft charcoal we shall derive but little benefit, at least where it is necessary to take the quality of the iron into consideration."

The following tables, embodying the general results of an extended series of experiments on the relative strength and other mechanical properties of cast iron, obtained by the hot and cold blasts, are extracted from a report presented to the British Association (1837) by Messrs. Eaton, Hodgkinson, and William Fairbairn.

Of the three columns of numbers, the first represents the strength or other quality

In the cold blast iron, the second that is the hot, the third is the ratio of the yield point to the ultimate strength in per centages and the number of experiments from which the results have been deduced.

	Cold Blast.	Hot Blast.	Experiments.
Carron Iron, No. 2.			
Tensile strength in the per square inch	19,842 (7)	12,000 (7)	1000 + 100

Modulus of elasticity in lbs. per square	1,000 (1)	1,000 (1)	1000 + 1000
Specific gravity	7.000 (1)	7.000 (1)	1000 + 1000
Carron Iron, No. 2.			
Tensile strength	19,842 (7)	12,000 (7)	1000 + 100
Compressive strength	9,710 (4)	9,710 (4)	1000 + 100
Specific gravity	6.000 (4)	6.000 (4)	1000 + 1000
Carron Iron, No. 2.			
Tensile strength	14,000 (4)	14,000 (4)	1000 + 1000
Compressive strength	13,000 (4)	13,000 (4)	1000 + 1000
Specific gravity	7.100 (1)	7.100 (1)	1000 + 1000
Devon Iron, No. 3.			
Tensile strength	17,000 (1)	15,000 (1)	1000 + 1000
Compressive strength	10,000 (4)	10,000 (4)	1000 + 1000
Transverse strength	10,000 (4)	10,000 (4)	1000 + 1000
Power to resist impact	1000 (1)	1000 (1)	1000 + 1000
Transverse strength of bars one inch square	400 (1)	400 (1)	1000 + 1000
Ultimate deflection of do. in inches	1.4 (1)	1.4 (1)	1000 + 1000
Modulus of elasticity in lbs. per square	1,000 (1)	1,000 (1)	1000 + 1000
Specific gravity	7.072 (1)	7.072 (1)	1000 + 1000

These results contain nearly the whole of the information afforded by the investigation. From the numbers in the tables, it will be seen that in Hot blast iron No. 1 cold blast somewhat surpasses hot blast in all the following particulars.—1, direct tensile strength; 2, compressive strength; 3, transverse strength; 4, power to resist impact; 5, modulus of elasticity or stiffness; 6, specific gravity; while the only numerical advantage possessed by the hot blast metal is that it bends a little more than the cold before it breaks. In No. 2 the advantages of the rival kinds are more nearly balanced, still rather in favour of the cold blast. No. 3 hot blast Carron iron resists both tension and compression better than cold blast of the same denomination; and No. 3 hot blast from the Devon works in Scotland is remarkably strong, while No. 3 cold blast is comparatively weak, notwithstanding its high specific gravity. On the whole it would appear from the experiments, that while the irons of No. 1 have been somewhat deteriorated in quality by the hot blast, those of No. 2 have been benefited by its molifying powers; while those of No. 3 have been but very slightly affected; and from the evidence brought forward, it is rendered highly probable that the introduction of a heated blast, whilst it has, perhaps, to a certain extent, injured the softer irons, has improved those of a harder nature; and considering the small deterioration that the irons of the quality No. 2 have sustained, and the apparent benefit of those of No. 3, together with the saving effected by the heated blast, there seems good reason for the process becoming so general as it has done.

The following general summary of results, as derived from the experiments of Messrs. Hodgkinson and Fairbairn on the transverse strength of hot and cold blast iron exhibits at one view the ultimatum of the whole investigation.

	Ratio of Strength that of Cast Iron being represented by 1000.	Ratio of Powers in static Impact: Cast Iron being 1000.
These irons are from Mr. Hodgkinson's experi- ments:—		
Carron iron, No. 2 - - - - -	1000 : 990.9	1000 : 1005.1

Mean - - - - -	1000 : 1024.8	1000 : 1226.3

Dr. Thompson's chemical examination of several samples of hot and cold blast iron is appended to this report. According to the experiments of this distinguished chemist, iron smelted by hot blast contains a greater proportion of iron, and a smaller proportion of silicon, carbon, and aluminum, than when smelted by cold air. The mean specific gravity of 8 specimens of Scotch cold blast iron No. 1 was 7.074; the mean of 5 specimens of hot blast from the Carron and Clyde iron works was 7.0623, so that the density of cold blast iron is less than that of hot. The mean of 6 analyses of cold blast iron No. 1 gave 34 atoms of iron, 1 atom of carbon, silicon, and aluminum; the proportion of these three constituents being very nearly 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminum, consequently Scotch cold blast iron consists of 20 atoms of iron (with a little manganese), 4 atoms of carbon, 1 atom of silicon, and 1 atom of aluminum. The mean of 6 analyses of hot blast iron No. 1, gave 6 atoms of iron and manganese to 1 atom of carbon, silicon and aluminum, from which it would appear that cast iron smelted with a hot blast is purer than when the blast is cold. This however, is not the case, as the numerous analyses of both varieties that have been made during the last few years concur in proving. Hot blast grey iron smelted with mineral coal contains a much higher percentage of silicon than the same variety of cast iron smelted from the same ores by cold blast, in other respects, provided the process of reduction is complete, i.e. when little or no iron passes off with the slag, there is very little chemical difference between the two varieties, as will be seen in the following table, which contains the results of a series of analyses of hot and cold blast iron, which we have lately had occasion to make, under circumstances peculiarly favorable for instituting the comparison, the furnaces working with the same ores, and making the same class of iron, viz. good No. 3 grey pig.

The true reason of the frequent inferiority of hot blast iron has been correctly given by Mr. Blackwell. Furnaces blown with heated air exert greater reductive power

than those in which a cold blast is used. This has led, since the introduction of hot blast, to the extensive use in iron smelting of refractory coals so thoroughly selected, a large part of which have been ores of a coarse calcareous to produce soft iron, and is in fact the use of ores of this nature, far more than from any deterioration in quality, arising from a hot blast, that this inferiority of hot blast iron is to be ascribed.

Conditions of the waste gases given off from the furnace head.—The agent in the blast furnace by which the oxide of iron is reduced is carbonous gas, the presence of which therefore in great extent is indispensable to the operation of the furnace. The flames rising from the heated head, which make a blast furnace at night such an imposing object, are consumed principally by the combustion of this gas, in coming into contact with the oxygen of the atmosphere; the attention of practical men was first called to the enormous waste of heat which this carbon flame entailed by Messrs. Hansen and Moller, and the application of the gas to a useful purpose may be ranked next to that of the heated blast, as the most important of the recent improvements in the iron manufactory. The gases evolved from the furnace when coal is used as the fuel, contain the following constituents, viz. nitroge, ammonia, carbonous gas, carbonic oxide, light carburetted hydrogen, sulphur gas, carburetted hydrogen of carbonaceous composition, hydrogen, sulphuretted hydrogen, and aqueous vapour. The nature of the combustible gas stands in a relation so intimate to the changes suffered by the materials put into the furnace, that its different composition in the various regions of the furnace indicates the changes suffered by the materials introduced as they descend in their way to the entrance of the blast. Now as the examination of this column of air in its various heights in the furnace must be the key to the question upon which the theory and practice of the manufacture of iron depend, it was of the first importance to subject it to a rigid examination; this accordingly has been done by the above-named eminent chemists, and subsequently by Flebman. We shall return to a summary of the results they obtained presently, confining our attention at present to the composition of the gases at the mouth of the furnace, and to the methods which have been adopted to utilise them.

In order to arrive at a knowledge of the composition of these gases, M. Hansen first studied minutely the phenomena which would ensue were the furnace filled with fuel only: by a careful distillation of a known weight of coal, and analysing of the products, he obtained results embodied in the subjoined table:—

Carbon	68.925
Tar	13.250
Water	7.460
Light carburetted hydrogen	7.441
Carbonic oxide	1.135
Carbonic acid	1.073
Condensed hydrocarbon and olefiant gas	0.753
Sulphuretted hydrogen	0.549
Hydrogen	0.499
Ammonia	0.211
Nitrogen	0.035
	100.000

Now, in the furnace, the oxygen introduced by the blast is consumed in the immediate vicinity of the tuyère, being there converted into carbonic oxide, and the coal loses all its gaseous products of distillation much above the point at which its combustion commences, near in fact, the top of the furnace; the fuel with which the blast comes into contact is therefore coke, and upon calculating the amount of carbonic oxide produced by the combustion of 68.925 per cent. of carbon, and the nitrogen of the air expended in the combustion, we get as the composition by volume of the gases escaping from a furnace filled with Gasforth coal the following:—

Nitrogen	62.479
Carbonic oxide	13.173
Light carburetted hydrogen	2.527
Carbonic acid	0.139
Condensed hydrocarbon	0.151
Sulphuretted hydrogen	0.091
Hydrogen	1.431
Ammonia	0.070
	100.000

of the fuel is lost in the form of combustible matter still fit for use, and that only 1.46 per cent. of the whole fuel is retained in carrying out the process in the furnace.

The temperature which should be produced by the flame of the furnace gases when burnt with air, is found by dividing the units of heat, viz. 84374 arising from the combustion of 1 kilogramme of the gases by the number remaining when the quality of the products of combustion is multiplied by their specific heat (1.4600 + 0.0001) we thus get the number 57800° F., but this is below the truth, inasmuch as there is an accession of combustible gases at the mouth of the furnace, arising from the decomposition of the lower portions of the combustion of the coal in its passage over the red hot fuel. Making proper allowance for this, and using numbers derived from actual experiments, Messrs. Bunsen and Playfair calculated the temperature of the gases when generated under favourable conditions at 7814° F., and even this may be increased to 8000° F., a temperature far above that of most fires, by the using a blast sufficiently heated. In no long time was gas, capable of being put to use, to remove them from the furnace till they really are waste, that is, until they have done their work in the furnace; it is obvious that no combustible matter could be removed from the lower regions of the furnace without seriously deranging the operations related to the reduction and smelting of the ore. In order to remove the gases efficiently, and without injury to the working of the furnace, and in such a state as will permit their combustion to be effected with most advantage, the height of the furnace must be raised, the full width of the mouth being retained, and the gases must be withdrawn sufficiently far below the mouth for them to be obtained dry, and also beneath the point where they begin to enter into combustion from contact with the atmospheric air.

Various modes of collecting the gases have been tried; the best seems to be that adopted at Ebbw Vale, Sirhowy, and Cwm Celyn. A funnel-shaped casting, equal in its largest diameter to the throat of the furnace, projects into the interior a depth of 4 or 5 feet; the grid at the bottom, from 3 to 5 feet in diameter, is closed by a conical casting, the apex upwards, from which a chain proceeds to a lever having a counterpoise at the other end. (See fig 1000.) The materials are filled into the funnel-shaped receptacle, and are charged into the furnace with a uniform distribution, by lowering the cone by means of suitable machinery, which again returns it to its place when emptied. The circular space around the funnel, inside the furnace, forms a chamber

for the reception of the gases, from which they are conveyed by brick tunnels or iron piping to the place of combustion. The whole arrangement will be clearly understood

by an inspection of the accompanying plans, *Figs. 1005, 1006, 1007, 1008, 1009*, kindly furnished to the writer by the proprietor of the Cwm Celyn and Blaenau Iron Works.

Fig. 1007 shows the plan of extracting the gases which is adopted at the Brynbo Iron Works, near Wrexham, the same being the patent of C. E. Darby.

It consists of a large pipe or tube inserted into the middle of the top part of the furnace, which descends a short distance down into the materials, and is carried over the top of the side of the furnace in the form of a syphon, a continuation of which pipe is taken to the boilers, or hot air stoves, where the gas is burned in the usual way. The principal advantage claimed by this method, is that it puts no check on the free escape of the gases, by which the driving of the furnace is impeded, and the quality of the iron deteriorated. The patentee estimates the saving of fuel with two furnaces making 240 tons of iron per week, by applying the gas to the blast engine boilers and hot air stoves, at 1200 *l.* a year. *Tons* :—Consumption of fuel at engine and stoves equal to 7 cwt. of good coal per ton of iron, made at 3½ per cwt., is 24.00 *l.*, say 24. per ton on 12,480 tons, or 12480 *l.*

The causes of derangement in the working of blast furnaces when the gases are drawn off to be utilised elsewhere, have been diligently studied by Mr. George Parry, of Ebbw Vale; and he has kindly furnished me with the following resume of his observations, for insertion in this article.

The manner in which the waste gases were formerly collected, was by sinking an iron tube, 7 feet deep into the throat of the furnace, the diameter of the tube being

about 3 feet less than that of the throat, thus leaving an annular space of 18 inches between the walls of the furnace and the sides of the tube. From this space the gases were allowed to pass off by the pressure within the furnace, through a pipe which penetrated the ring and walls. When the tube was kept full of molten metal, about

only of the gas escaped into the open air, the rest passing into the annular chamber; and when this state of things was assumed, those troublesome adhesions of masses of semi-fused materials above and around the bushes, technically termed "seafish," occurred, with the usual accompaniments of black cinder and inferior iron. It is evident that when the tube was kept full of minerals, the contents acted as a loose stopper to the current of hot gases forced up by pressure from beneath, and diverted them towards the annular space where there was no such resistance, thus leaving the interior of the central parts of the furnace insufficiently supplied with the upward current, and consequently with heat; the minerals, on the other hand, surrounding this cold central core, were supplied with more than their usual quantity of heat, as was evidenced by the burning of tuyères, and by the destruction of the brickwork in their neighbourhood. In this state of things, the ores in the external portions of the furnace would become reduced and converted into grey metal; while those in the central portion would, according to the degree of deviation of the ascending current of heated gases from them, descend to the point of fusion either thoroughly deoxidized, and slightly carbonized, or possibly with a portion still in the state of oxide, and mixing there with the properly reduced ores, enter into fusion with them, producing a mixture of iron which must necessarily prove of inferior quality, and a black cinder from the unfused oxides. When the iron tube in the throat of the furnace was kept only partially filled with minerals, much more gas escaped into the open air, as might have been expected, and consequently more traversed the central parts of the furnace; and it was always observed that when that mode of filling was adopted, the furnace worked much better; but then the object, viz. that of economizing the gases, was not attained. Differently formed furnaces were found to be disturbed in different degrees by this system of drawing off the gases: the old conical narrow topped furnaces were affected very much less than the improved modern domed top furnaces of large capacity, from which all attempts to take off any useful portion of the gases proved absolute ruin. It might be argued, that as the same quantity of blast and fuel were used as heretofore, the ascending current of heated gases ought to produce the same deoxidizing and carbonizing effect on the superincumbent mass, whatever direction they might take in making their escape at the upper region of the furnace; for if the central part should not have been sufficiently acted upon, the external annulus would have more than its usual share of chemical influences. But when it is considered that iron is only capable of taking up a certain quantity of carbon, and no more, it follows that after having received this dose, its further exposure in the external parts of the furnace where the heated gases should can do nothing towards supplying the deficiency of carbon in the metal reduced in the central part. From these considerations it became evident, that no system of drawing off the gases around the sides, whether by the insertion of an iron tube into the throat, or by lateral openings through the walls into a chamber surrounding the top of the furnace, can be adopted without more or less injury to its action; and that the only unobjectionable mode would be to take the gases from a chamber above the surface of the minerals, thus equalizing the pressure on the whole sectional area of the mouth, and thereby allowing an equally free flow for the ascending current up the middle, as well as up the sides of the furnace. By this method the whole of the waste gases would become utilised, instead of a portion only, and the furnace would be restored to its original state, inasmuch as the direction of the flow of heated gases would not be interfered with by unequal resistance. To form this chamber, the furnace must be covered in, and fed through a hopper, a plan long adopted at the Codner Park Iron Works, with the supposed advantage of scattering the minerals around the sides of the furnace, and preventing their accumulating in the centre; a conical charger of this description, but fixed in the throat of the blast furnace, was in use at the Cyfartha Works more than half a century ago, the minerals being thrown by baskets to the centre of the cone, and allowed to roll down to the sides of the furnace, thus giving a cup form to the surface of the minerals, the larger lumps of course rolling to the centre, and affording a freer passage in that direction for the upward current. It was not, however, until January, 1831, that a trial was made, at the Ebbw Vale Works, of an apparatus of this description for collecting the gases. It was then supplied to one of the old forms of conical furnace with a narrow top, and the trial proved eminently successful, the furnace producing any quantity of iron required according to the burden, as usual. Several other furnaces were similarly furnished in and around the neighbourhood, and it was now thought that the principle of taking off the gases from a chamber above the surface of the minerals, together with the conical mode of charging, were the only indispensable conditions to success for all furnaces; and some even which were originally built too narrow at the mouth, were actually improved by the new method of charging, which did not allow of the sur-

form of the chimney rising higher than about 6 feet from the top; thus giving to the furnace a diminished height, and so a preponderance of its central charge a wider space. Further experiments, however, demonstrated the fallacy of this general conclusion.

A large lined furnace was furnished with the same kind of charging apparatus which proved so successful in former attempts, but to the advantage of all it turned out a complete failure, the same arrangements to measuring as in the former trials, where a portion of the gases only was retained, by adding a little hot blast to the top. Now the furnace could not be kindled to within 2 or 3 feet of the top, and as that depth the diameter was 18 ft. 6 in., owing to the steepness of the dome the actual width of the furnace was therefore 37 feet high, diameter of 44 feet, with a mouth 13 ft. 6 in., instead of 8 ft.; and at the same time the height of the dome against the smooth sides of the walls as they descended to each other in the more pointed regions of the furnace, a much freer descent of the gases up the sides than before, and on boring a hole through the top of the furnace, in the neighbourhood of the furnace, it was found that 2 feet in, the sides and other interior were of a white heat, but a little further on towards the centre, lumps of black burning coal were found, with iron ore which had not even at that point melted. The charging apparatus had now raised with the furnace 3 feet, and the minerals drawn up an immense pile in the charging cup, thus enabling it to be kept full to within a short distance of the old mouth, after which the furnace worked as usual. That diminished height was not the cause of the bad working of the furnace was afterwards proved, the furnace having been blown out for repairs, and re-lined with brickwork, giving it that form and proportion deemed necessary, from the experience gained; the height being now only 37 feet instead of 44, and the diameter of the mouth 7 ft. 6 in., or one half of that of the former. The same charging apparatus which failed before, mounted 6 feet above the mouth, was used, and the furnace has now been working most successfully for 2 years, turning out as much as 160 tons of grey pig iron per week, or what has been found for white iron, 200 tons; economizing the waste of the gas, and at the same time the control of the manager as any furnace, either could it put out iron in quantity he expected to be. It is clear, therefore, that the covering of the top has nothing whatever to do with the action of a furnace kept full to the mouth, and having the proper form and proportion as from that point downwards. The mouth must be understood to be that part of the furnace which represents the mean height of the surface of the minerals, and not the top of the chimney, and the proper arrangement should be that the diameter to the bottom or widest part, and when the latter should be with reference to height in order to secure a uniform downward effect on the quality of the iron made, and on the yield of fuel. The cause of imperfectness exists only when the isothermal lines in the furnace are parallel to the horizon. The temperature of the minerals at any given height above the tuyeres being the same through the whole horizontal sectional area at that height, and consequently arriving at the zone of fusion in an equally prepared state. If the mouth of the furnace be too wide, the heated gases have a greater tendency to pass up the sides than through the centre, thus destroying the horizontality of the lines of equal temperature, and giving them a curved form with the convex side downwards; hence ores at different temperatures, and of various stages of preparation, will occupy any given horizontal sectional area of the furnace; these descending together and mixing in the zone of fusion, will produce evils in proportion to the extent of the deviation of the curves from a horizontal line. On the contrary, if the mouth of the furnace be too narrow in proportion to the other parts, we may expect an undue portion of the gases to pass up the centre, leaving the minerals around the sides comparatively unacted upon. It is easy to see that evils of the same kind as before must exist here, the isothermal lines becoming now convex downwards, instead of concave, giving as before, through any horizontal section of the furnace, ores at various temperatures, and at different stages of oxidation or carburization, according to the depth which they may have attained in the furnace. There are several instances of furnaces originally built with too narrow tops, being greatly improved by widening them; this may conveniently be done by feeding them through a conical charger, which by lowering the surface of the minerals virtually increases the width of the mouth: on the other hand, furnaces having the opposite defect of being too wide at the top, may be benefited to some extent, provided the walls are nearly perpendicular, or do not widen too rapidly downwards, by employing as large a cone as it is possible to work in the throat; for by the use of this feeder, the minerals must fall close to the sides, and the larger lumps roll to the axis of the furnace, and so facilitate the passage of the gases in that direction, broadening the surface a concave or cup form, and consequently a diminished height and resistance to the upward current in the middle. This principle of improving the

charging of such blast-furnaces is easily carried out to some extent in the open top furnaces where the gases are wasted. The charging plate is so placed as to prevent the nose of the barrow from passing any distance into the furnace; the minerals are thus discharged close to the side, the larger lumps have a tendency to roll over towards the centre, leaving the smaller at the rim walls, to check the upward current in that direction.

The above remarks will generally assist in furnishing an answer to the oft-repeated and very important question, "What form and proportions should a blast-furnace have to produce the best results in quality of iron, and in economy of fuel, whether worked on the open-top principle, or enclosed for the purpose of utilizing the waste gases?" Experience has proved that when the mouth of the furnace is one-half the diameter of the widest part, good work is obtained, and that any deviation from that proportion, if in excess, has been productive of great derangement in its action. The height of the furnace should also bear a certain proportion to the greatest diameter, in order to secure an uniform flow of the ascending current through all its parts; for if the widest part bear too great a relation to the height, the bushes must necessarily be of a low make, and consequently the minerals around the sides near their top be at too great a distance out of the direct line of passage of the ascending current, and consequently remain only partially prepared for fusion.

The proportions recommended by Mr. Parry, and which have been practically found most satisfactory in several instances, are as shown in fig. 1011. The mouth 1011 must be at a less depth than its own diameter. The shape of the furnace to this depth should be formed slightly *cambré* (cambered), for the purpose of giving to that region a larger capacity than would be obtained by a conical form. The radius of the curve should be at right angles to the axis of the furnace, and formed by a prolongation of the line representing the greatest diameter. When the radius is set at a great angle with this line, which is often done to give greater capacity to the widest part, the distortion produced by the obliqueness of the curve may leave a segment of the internal surface upon which the gases in their passage to the mouth, encounter greater evils than would be compensated for by increase of capacity. The curve is continued below the widest part of the furnace till it meets the top of the bushes *dd*, the angle of which should not be less than 70° , and start from the point of the tuyeres *ff*. The depth also from the widest part to the tuyeres should not be less than its own diameter plus half the diameter of the tuyeres. These proportions give a blast-furnace, of any determinate height fixed upon, the largest possible capacity it is capable of receiving, while remaining free from any distortion of form, likely to give a place for minerals to lie out of the way of the action of the upward gaseous current; when the height exceeds the proportion to its greatest diameter indicated in the figure, an unnecessary sacrifice in its capacity is the only loss entailed. The height above the mouth must be regulated by the kind of hopper used for charging, where it is intended to carry off the gases.

Doubtless when the true principle of collecting these gases without injury to the blast-furnace becomes more generally known, attention will be directed to the easiest and most convenient mode of introducing the minerals. The conical charger has only one disadvantage, that namely of allowing a great waste of gas during the charging; probably some kind of revolving hopper may be contrived to remedy this defect. It is of course assumed that the furnace is supplied with a proper quantity of blast, and of a density proportionable to the diameter across the tuyeres, so as to maintain a *convective* combination of the fuel to the very centre of the hearth, the top of which is indicated by the letters *ee*, for unless this is attained, a cold cone of mineral will remain in the centre, and produce derangements which no degree of perfection in the form of the furnace in the higher region can remove.

Theory of the blast-furnace.—Analyses of the gases from a furnace at Alfreton in Derbyshire, at various depths below the surface, gave to Messrs. Henson and Playfair the results embodied in the subjoined table. The furnace was supplied with 80 charges in the course of 24 hours, each charge consisting of 390 lbs. of coal, 420 lbs. of calcined ironstone, and 170 lbs. of limestone, the product being 140 lbs. of pig-iron. The gases were collected through a system of tubes of malleable iron, 1 inch in

diameter, and were removed in glass tubes 4 inches long, and $\frac{1}{2}$ of an inch in diameter. This was known to M. Bunsen as a gas analyst is a guarantee of the accuracy of the determinations.

Composition of the Gases taken from different depths in the Furnace.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.
	1 R.	1 R.	11 R.	11 R.	17 R.	22 R.	28 R.	33 R.	34 R.
Nitrogen	79.2	64.77	29.47	26.3	76.46	66.46	66.78	67.71	68.64
Carbonic acid	7.77	2.42	2.41	2.35	11.43	10.78	6.77	10.74	10.74
Carbonic oxide	34	67.34	67.12	15.2	19.17	17.42	27.05	27.48	27.63
Light carburetted hydrogen	2.73	9.23	4.76	7.13	9.36	6.46	1.64	2.12	2.12
Hydrogen	0.73	0.69	9.94	1.01	7.75	1.87	4.96	5.47	5.73
Olefiant gas	0.47	0.46	0.71	.57	2.38	2.27	2.26	2.72	2.76
Cyanogen	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	1.34

From these analyses it appears —

1. That at a depth of 34 feet from the top, with a 2 feet 9 inches of the layer, the gas was entirely free from carbonic acid, but contained an appreciable quantity of cyanogen.

2. That the nitrogen is at a minimum at 14 feet.

3. That carburetted hydrogen is found so low as 24 feet, indicating that at that depth, coal must be undergoing the process of coking.

4. That hydrogen and olefiant gases are at a maximum at 14 feet.

5. That the proportions between the carbonic acid and carbonic oxide are irregular, which is probably to be explained by the fact that water is decomposed as its vapour passes through the layers of hot coal.

The average composition of the gas collected from the main shaft work in the blast furnace is somewhere between the two following numbers:

Nitrogen	60.307	77.674
Carbonic acid	8.374	9.127
Carbonic oxide	27.848	21.012
Light carburetted hydrogen	2.528	2.743
Hydrogen	1.126	1.272
Olefiant gas	0.112	0.062
Sulphuretted hydrogen	0.043	0.003
Ammonia	0.023	0.113
	100.000	100.000

The proportion of nitrogen to oxygen as an average deduced from these analyses is 79.2 to 27. The product of the combustion of coal gives the same proportions as those existing in atmospheric air, viz. 79.2 : 21.012. The excess of oxygen must therefore depend upon the carbonic acid of the limestone, and the oxygen of the ore given to carbon during the process of reduction. Now, so at a depth of 24 feet the gas collected contained 27.6 and 26.5 oxygen to 79.2 nitrogen, it is seen that at this depth the gas must already have accumulated all the oxygen of the ore, and the carbonic acid of the limestone; and the conclusion is drawn that in hot blast furnaces fed with coal, the reduction of the iron and the expulsion of the carbonic acid from the limestone takes place in the bosom of the furnace. The exact region of the furnace in which the melting of the iron and the formation of slag are effected is not exactly defined, but it is assumed that the point of fusion is at the top of the hearth. The region of reduction in a furnace smelting with coal must be much lower than when the fuel is coke or charcoal, because a large portion of the body of the furnace must be taken up in the process of coking, and the temperature is thereby so depressed, that it is sufficient neither for the reduction of the ore, nor for the expulsion of carbonic acid from the limestone.

The mean general results obtained by M. Edelman from a charcoal furnace at Cleval are given below. The methods of analysis adopted by this chemist were altogether different from those employed by Messrs. Bunsen and Playfair. For details we refer to his memoir in the *Annales des Mines*, vol. xix. p. 69, 1851.

No. of analysis .	I.	II.	III.		IV.	V.	VI.	VII.
Depth	3 ft. 3 in.	3 ft. 3 in.	9 ft. 9 in.	9 ft. 9 in.	11 ft.	14 ft.	17 ft.	17 ft. 6 in.
Carbonic acid	17.0	11.0	4.14	4.23	0.45	0.47	0.45	0.45
Carbonic oxide	35.0	29.0	31.0	31.34	30.0	30.47	32.15	32.0
Hydrogen	0.0	4.31	2.04	2.77	1.06	1.00	1.13	0.99
Carbonated hydrogen	0.00	1.23	0.31	0.77	0.34	0.31	0.10	0.25
Nitrogen	35.0	30.0	60.93	60.66	63.04	62.64	61.22	60.17
Totals	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00
Oxygen, per 100 nitrogen	47.5	49.0	32.7	32.7	29.3	29.3	30.7	30.0
Carbon vapour, per 100 nitrogen	0.0	31.7	25.6	29.0	29.0	29.0	30.7	30.0

I. Gas taken a short time after the introducing of the charge; II. the same taken a quarter of an hour after charging; III. gas collected through a cast iron tube four inches in diameter, it rushed out with a noise and gave a sheet of flame, carrying with it particles of charcoal and dust; IV. gas collected by boring the masonry; it rushed out violently, burning with a blue coloured flame; V. the same taken an hour after; VI. gas collected by boring the masonry at the back of the furnace about $\frac{1}{2}$ foot above the tuyère; it burnt with a white flame giving off fumes of oxide of zinc; it was collected through porcelain tubes; VII. gas collected through gun barrels lined with porcelain, it was evolved with sufficient force to project scoria and even cast iron.

The furnace was working with cold blast under a pressure of $\frac{1}{4}$ inch of mercury. The charges had the following composition:—Charcoal, 255 lbs.; minerals (various), 337 lbs.; limestone, 251 lbs. Thirty-two charges were driven in twenty-four hours; the furnace was stopped after every twenty charges; the produce being 3970 lbs. of black cast-iron; the daily yield being about 6175 lbs.

The experiments show that while the carbonic acid progressively diminishes downwards, the carbonic oxide progressively increases, the former altogether disappearing at a depth of 37 feet. On examining the numbers representing the oxygen and carbon referred to 100 nitrogen, it is seen that they diminish progressively to a depth of 19 feet, the oxygen combined varying from 47.5 to 29.2. The proportion of carbon in the same zone rises from 25.5 to 32.8; a result brought about as much by the carbonic acid disengaged from the minerals as from the gaseous products of the distillation of the charcoal. It is seen that the reduction of the mineral is already considerably advanced at the depth of 19 feet; and this, so to speak, without any consumption of charcoal, but through the conversion of carbonic acid into carbonic oxide. The hydrogen decreases as the carbonic oxide increases; showing that this gas exercises no influence in the reduction of the ore.

The results obtained by M. Ebelmen from a coke furnace at Seraing were as under:—

No. of experiment	I.		II.		IV.		V.	VI.
Depth	1 ft.	1 ft.	4 ft.	9 ft.	14 ft.	16 ft.	19 ft.	19 ft.
Carbonic acid	11.30	11.26	9.03	1.34	1.08	1.13	0.10	0.10
Carbonic oxide	30.41	28.63	20.06	23.96	25.3	25.0	30.0	30.0

I. Gas obtained by plunging an iron tube, three centimetres in diameter, about one foot into the furnace; II. the same; the gas burnt spontaneously; IV. two consecutive analyses of the same gas; V. the gas was collected by an iron tube; VI. gas collected by piercing the masonry two feet above the tuyères; the gas was accompanied by fumes of cyanide of potassium, but no cyanogen could be detached.

The furnace was 50 feet high; the air was supplied through two tuyères, and was Vol. II.

found to be 212. It was driven at the rate of 15.94 gallons per minute under a pressure of 3 of mercury. The gases were composed of, uncombined minerals, 1434 lbs.; hydrogen, 1434 lbs.; methane, 91 lbs.; coke, 1763 lbs. The metal was run every twelve hours, and 17,000 lbs. of white crystalline cast-iron obtained, which was run in thin plates and taken directly to the puddling-furnace. The yield of the mineral was 40 per cent., and the consumption of coke 1400 per 1000 of cast-iron, rising from 1800 to 2000 per 1000 of iron when the furnace was working in ordinary iron.

The analyses show a rapid decomposition of carbonic acid, and indicate that in the upper regions of the furnace an equilibrium relation of iron takes place by the escape of carbon under the influence of the high temperature of the ascending gases. Between one and nine feet the reduction is complete. The reduction of the ore takes place at this region by the conversion of iron oxide into iron carbide, and without change of volume and without consumption of fuel. The action in the by-product is too small to induce a supposition that a great volume of hydrogen is evolved; any notable quantity of carbon. The gases collected at a depth of about 12 feet represent about the mean composition of the gaseous mixture; from that point to a depth of 40 feet, two-thirds of the total height of the furnace, the gases do not sensibly vary, and are composed almost entirely of carbonic oxide and nitrogen. At 12 feet the oxygen is to the nitrogen as 25.9 to 100; in atmospheric air it is as 26.3 to 100. The difference, .4, represents the oxygen arising from the reduction of the oxides of iron constituting the *burge cinders*, which then is seen to take place between the tuyere and a depth of 12 feet. These oxides are well known to be decomposed with difficulty, but they are reduced at the high temperature prevailing in that zone of the furnace, and their reduction gives rise to a corresponding quantity of carbonic oxide, to a consumption of fuel, and to a considerable absorption of latent heat. The other minor ores are reduced higher up in the furnace, and this is common to all coke furnaces, being due to the high temperature of the ascending gases, a temperature much higher than exists in charcoal furnaces, a far larger quantity of combustible being consumed. Hence it is that iron ores can be economically used in coke furnaces, while in charcoal furnaces the introduction of small quantities only alters the working of the furnace, makes the iron white, and corrodes rapidly the walls of the furnace in consequence of the imperfect reduction.

From his radiometric experiments on the gases from coke and charcoal furnaces, Elmheden deduces the following conclusions:—

1. That the amount of carbonated hydrogen is too small to exercise any influence over the chemical phenomena of the furnace.
2. That the atmospheric air thrown into the furnace by the *tuyère* produces successively carbonic acid and carbonic oxide, at a small distance from the point. The first of these reactions gives rise to an exceedingly high temperature; the second, on the contrary, causes a great absorption of latent heat, and a corresponding lowering of the temperature of the gaseous current. The limits of the *zone of fusion* bears relation to the space in which the transformation of carbonic acid into carbonic oxide takes place.
3. That the ascending current consisting of carbonic oxide and nitrogen, with a little hydrogen, produces in ascending two distinct effects: it communicates one part of its sensible heat to the materials of the descending column; it becomes charged with all the volatile products disengaged at different heights, and it reduces the oxide of iron to the metallic state. Sometimes this transformation gives rise to an increase in the quantity of carbonic oxide; sometimes, on the contrary, it effects the conversion of carbonic oxide into carbonic acid without change of volume, and without consumption of fuel. Whenever the reduction of oxide of iron takes place with the production of carbonic oxide, there is a consumption of fuel, and an absorption of latent heat. It is essential, therefore, to the good working of the furnace, that the minerals should arrive completely reduced to that part where the temperature is sufficiently elevated for the conversion of carbonic acid into carbonic oxide by contact with carbon; this condition is nearly always realised when the oxide of iron is in a free state in the mineral. The reduction of the oxide when in combination with silica requires, on the other hand, a high temperature, and it can only take place in that zone of the furnace where the carbonic acid has completely disappeared.
4. That the zone where carbonic oxide exists alone is much more extended in coke than in charcoal furnaces, and is nearer the mouth in the former than in the latter; it falls lower, however, in the cylinder with hot blast, the quantity of heat remaining the same.
5. That the volatile gaseous matters from the distillation of the charcoal pass into the escape gases, and exert no influence on the reduction of the minerals.

The mutual relation of the carbonic acid and carbonic oxide, which is observable

In the analyses of Ebelmen, is not far from those of Bunsen and Playfair; this is attributed by Ebelmen to the circumstance that the latter chemists collected their gases through narrow iron tubes, which, becoming intensely heated and partially clogged by the fragments of ore and fuel introduced by the rapid stream of gas, so modified the composition of the gases, that the analysis, however carefully conducted, could not represent accurately their real composition. Ebelmen collected his gases through wide tubes, and from the lower parts of the furnace, by piercing the solid masonry. It is obvious, however, that none but very general conclusions can be drawn from the analyses of the furnace gases, in whatever way they may be collected, for their composition cannot be the same under all circumstances, the nature of the fuel, the pressure of the blast, and (as Mr. Parry's experiments prove) the shape of the furnace itself, must each exert an influence in modifying the circumstances which affect their composition. Although, therefore, it is impossible to fix the precise regions of the furnace where the reduction of the oxide of iron begins to take place, that is, to define precisely the limits of the "zone of reduction," we may in considering the theory of the production of crude iron divide the furnace into four zones. 1. The zone of reduction; 2. The zone of carburization; 3. The zone of fusion; 4. The zone of oxidation. The zone of reduction will vary in extent, according as the furnace is working with coal or with coke; with hot blast or with cold. The zone of carburization commences just below the top of the blast, the reduced metal in a soft and malleable state here acquires, during its rapid working being retarded by the contraction which the gases of the furnace begin to undergo from this point downwards. As the carbonized metal passes through the zone of fusion it melts, together with the earthy matters which serve to protect it from the oxidizing effects of the fourth zone, that of oxidation, through which it passes in its passage to the crucible. If the temperature of the zones of fusion and oxidation be not much higher than the melting point of specular iron, the metal in the crucible will be white, with little or no graphite; and if the iron remain sufficiently long in the zone of carburization to take up the maximum quantity of carbon, it will be bright iron. The reduction of silicon appears to take place at about the melting temperature of specular iron: it exists therefore in small quantity in white iron, and in greatest abundance in the grey iron melted from refractory ores, which require a high temperature.

The proportion of carbonic acid in the gases obtained from different heights in a furnace, has been studied by MM. F. Montefiore Levi and Dr. Paul Schmidt (*Zeitschrift des Ingenieurvereins*, 1892). They found that the zone from which this gas is entirely absent is of very limited extent, for although it is not met with at a height of 8 feet from the tuyère, it exists at 9 feet to the extent of 4.78 per cent., above which point it diminishes up to 15 feet, where it is 0. From this point it again increases, amounting at a height of 30 feet to 3.5 per cent. It then gradually diminishes, until, at a point from 37 to 38 feet above the tuyère, it amounts to only 1.80 or 1.91 per cent.; after which it goes on increasing with rapidity and regularity up to the furnace mouth. The carbonic acid existing in the furnace gases between 15 and 30 feet is referred by these chemists to the decomposition of the limestone used as a flux; and its gradual diminution above this point indicates a reaction of considerable importance, that namely of the carbonic acid upon the ignited coke carbon being taken up and carbonic oxide formed. Now, the quantity of carbon taken up by 875 parts of carbonic acid to convert it into carbonic oxide, amounts to 75 parts, and as in the furnace experimented with, 20,000 kilogrammes of limestone, containing about 8000 kilogrammes of carbonic acid were consumed every 24 hours, a loss of fuel equivalent to 2173 kilogrammes of carbon was daily occasioned by the conversion of the carbonic acid into carbonic oxide, and this may be considered equivalent to 2173 kilogrammes of coke with 11 per cent. of ash. The heat absorbed by the conversion of the carbonic acid of the limestone into a gaseous state is found by calculation, taking the specific heat of carbonic acid at 0.22, and the heating power of coke at 6000, to be equivalent to that developed by the combustion of 322 kilogrammes of coke. Now it was demonstrated by Dulong that the quantity of heat disengaged in the conversion of carbon into carbonic oxide is much less than that disengaged in the conversion of carbonic oxide into carbonic acid, although the same quantity of oxygen is required in both cases. The conversion of carbonic acid into carbonic oxide by passing over ignited carbon, is essentially a twofold action; a combination of carbon with oxygen, and a decomposition of carbonic acid into carbonic oxide and oxygen; the former is accompanied by development, the latter by absorption of heat; the latter preponderates to such an extent as to indicate a loss of temperature equivalent to the heat developed by the combustion of 1609 kilogrammes of coke.

These considerations led the authors to employ barut lime in working blast furnaces, and thus to obviate the loss of heat; the results were not at first satisfactory, the management of the furnace being very difficult, and the slags black and pasty; but

consequently the working was regular and good, and the saving of coke and the increase of production are stated to have been very evident; moreover the raw iron was of better quality, and all the interior parts of the furnace, especially the tuyé pipe, remained in a much better state of preservation than when limestone was used. The following table shows the quantity of coke consumed for every 100 kilogrammes of raw iron, and the production during six months. The figures in the first column refer to the furnace, in which limestone alone was used; the second column to the same furnace, in which burnt lime alone was used; and the third column to the furnace in which limestone was used for three months, and burnt lime for the next thirty months.

	Quantity of Coke in kilogrammes consumed for every 100 kilogrammes of raw iron.			Production during 24 days, in kilogrammes.

The very regular and uniform results given in this table, show that by the use of burnt lime, the consumption of coke for every 100 kil. grammes of raw iron was reduced by 14 to 15½ kilogrammes, while at the same time the production of iron increased, within a certain period, as much as 23 to 24 per cent.

Hitherto the opinion of metallurgists, with regard to the use of burnt lime, was rather unfavourable than otherwise, but since the above experiments were made (at Ougrée), it has been employed with good results in England and Wales, and as much as 12 kilogrammes of coke have, it is stated, been saved for every 100 kilogrammes of limestone, which was replaced by 63 of burnt lime.

Varieties and chemical constitution of cast iron.—In commerce there are four principal varieties of cast iron, known respectively as Nos. 1, 2, 3, and 4, or *dark grey*, *bright grey*, *mottled*, and *white*; these terms, although convenient, do not, however, indicate the intrinsic value of the iron thus denominated, as the variable qualities of ore, fuel, and limestone may exercise such an influence on the resulting crude iron, as to render a low denomination of one manufacturer of greater commercial value than a higher denomination of other makers. The general characters of the four varieties are these:—No. 1. Colour, dark grey, in large rounded grains, obtained commonly near the commencement of the casting when the furnace is in good working order, and when an excess of carbon is present; in flowing it appears pasty, and throws out blue scintillations. It exhibits a surface where crystalline vegetations develop themselves rapidly in very fine branches; it congeals or fixes very slowly; its surface, when cold, is smooth, concave, and often charged with plumbago; it has but a moderate tenacity, is tender under the file, and susceptible of a dull polish. When melted over again, it passes into No. 2, and forms the best castings. No. 2, colour bright grey, of small-grained structure, and interspersed only with small graphite lamina; possesses great tenacity, is easily filed, turned, and bored; may even be hammered to a certain extent; does not readily crack from change of temperature. No. 3 is a mixture of white and grey iron. On *strongly mottled* iron, little stars and spots of grey iron are found, interspersed in bright or flowery iron; *weakly mottled* iron exhibits white specks on a grey ground. In *streaked* iron, grey iron is found above and below, and bright iron in the middle, with strong demarcations. No. 4. *White* iron varies from tin white to greyish white; it is very brittle, cracking easily, even by change of temperature; it is extremely hard, sometimes even more so than

hardened steel, so that it will resist the strongest file, and scratches glass easily. Fracture sometimes laminar, sometimes lamino-radiating, sometimes finely splintered, sometimes dense and conchoidal. As the fracture changes from laminar to conchoidal, the colour likewise varies from white to greyish. Mean specific gravity, 7.5. Expands less than grey cast iron when heated, cannot be welded, because it becomes pasty at the very lowest welding heat. When heated to the melting point it does not suddenly pass into the fused state like grey pig iron, but is converted before fusing into a soft pasty mass. In this variety of pig iron the whole of the carbon is united to the iron; it is never used for casting, but always for conversion into malleable iron. The bright iron obtained from apathic iron ore contains the largest proportion of carbon (3.3 per cent. according to Karsten). A white iron is always the result of a derangement in the working of the furnace, though it by no means follows that when the iron is white the furnace must necessarily be in a deranged state, the presence of manganese, for example, has a tendency to make white cast iron; but the quality may be excellent. The white iron resulting from derangement flows imperfectly, and darts out in casting abundance of white scintillations; it fuses very quickly, and on cooling exhibits on its surface irregular asperities, which make it extremely rough; it is exceedingly hard, though it is easily broken, the fracture being radiated and lamellar; the bar iron it affords is of inferior description. This kind of iron is always produced when the furnace is carrying a heavy burden of large cinders containing sulphur and phosphorus.

Thus there are two distinct kinds of white cast iron: 1st. That obtained from ores containing a large proportion of manganese crystallising in large plates; this variety is highly prized for making steel. 2nd. That resulting from a heavy mineral burden, or from a general derangement of the furnace, or from the rapid cooling of fused grey iron crystallising in small plates; both are hard and brittle, the first more so than the last. Cast iron, which by slow cooling is grey, becomes white when it is cooled rapidly; on the other hand, when white iron is melted and allowed to cool very gradually, a portion of the carbon crystallises out as graphite, and grey cast iron is produced.

In some iron works six varieties of pig iron are recognised, which may be classified thus:—1. First foundry iron, large crystals; 2. Second foundry iron, large and small crystals mixed; 3. Dark grey, all small crystals; 4. Bright grey; 5. Mottled; 6. White, verging on mottled.

The subjoined table exhibits the composition of some different varieties of Continental, English, and American crude irons. The methods of determining the various elements which nearly always accompany cast iron, are given at the end of this article.

a. Very grey pig, from Leestach in the Harz, cold blast; b. Mottled iron, from the royal works in the Harz, cold blast; c. Normal grey pig, from the same works, hot blast; d. Grey charcoal pig, cold blast; e. White pig from Farny, very short and brittle; f. American grey pig, charcoal; g. American mottled iron; h. American charcoal, white iron; i. German white charcoal iron, very crystalline; j. The same, but less crystalline; k. Grey Scotch coke pig, from the Calder Iron works; l. Scotch coke, No. 2 pig iron; m. Glenarries, No. 3 pig; n. Caubrookdale Lightstone best first foundry iron; o. Grey pig iron, from Dudley, Staffordshire; p. Ordinary Aberdare white pig; q. Grey slender pig; r. White crystalline pig iron, mottled from manganese ore; s. The same; t. The same; u. Ordinary white pig.

Besides the substances enumerated in the above table, other metals, such as copper, arsenic, chromium, titanium, cobalt, zinc, tin, aluminium, and the metals of the alkalis

iron does not take place, neither does pure carbene oxide carbon as iron when passed over the metal at a red heat the effect in the experiment above described may therefore be due to the carburized hydrogen evolved from the charcoal. Iron begins to take up carbon when heated only to the softening point, the carbon gradually penetrates the metal, converting it first into steel and then into cast-iron; conversely melted cast-iron gives up carbon to soft iron, which it converts into steel. When white iron (Fe°C) is heated with acids, nearly the whole of the carbon is eliminated in combination with hydrogen. Grey iron only gives up to hydrogen the carbon which was chemically combined with the iron, the uncombined carbon or graphite remains unacted upon; the dark spot produced upon grey iron by a drop of nitric acid arises from this separation of graphite. For the amounts of carbon in the different varieties of steel, see STEEL.

Phosphorus.—In very few specimens of crude iron is this element wholly absent; when it exists in small quantities only, it is said rather to improve the iron for castings, as it imparts to the metal the property of fusing tranquilly; in a larger proportion it weakens the iron. In like manner a very small quantity of phosphorus hardens bar iron without materially influencing the other properties, but when it exceeds 3 per cent. it renders the bar brittle, cold short, as it is termed. According to Schafhausen, both cast-iron and steel are improved by phosphorus and by arsenic; he found the latter in the celebrated Dannemora iron, and in the Lowmoor iron, and the former in the equally famous Rönneby (CCND) iron.

Sulphur. This element imparts to crude iron the property of becoming viscous, and of solidifying quickly with cavities and air-bubbles. It is not certain to what extent, or if at all, the presence of minute proportions of sulphur redacts either the tenacity or the toughness of cast-iron of given quality in other respects. It is stated in the Report of the Commission of Inquiry, as to the manufacture of cannon on the continent, on the authority of Schür and Mascherlich, that in certain Swedish works *pyrites* is thrown into the furnace with the other constituents of the charge, to produce the fine grey mottled iron required for gun founding, and it is added that the effect may be analogous to that of the oxidizing flame in a reverberatory furnace. It is certain that sulphur possesses the property of concentrating carbon in iron; and as mottled iron is a mixture of white and grey iron, it is not difficult to see how the addition of pyrites may determine the formation of this variety of cast-iron in a furnace, which without it would produce grey iron only; but it is scarcely credible that any intelligent founder would resort to such a method of making iron for casting cannon, in which the highest possible degree of tenacity is required. The fine grey mottled iron, which from its tenacity is known to be best fitted for large cannon, is said to be prepared without difficulty, by charging the furnace partly with roasted and partly with raw ore, and so regulating the blast that the yield shall be regular, and the slag nearly colourless; these two ores, having different degrees of fusibility, are reduced after different periods in the furnace, and hence afford one of them grey, and the other white iron, the result being, provided the minerals are properly proportioned, a mottled iron, harder and more tenacious than grey iron, obtained by mixing or by smelting in the cupola. It is desirable that the temperature of the furnace should be kept as low as possible, the production of dark grey graphitic iron resulting always from intensity of heat.

When sulphur is melted with iron containing the largest amount of chemically combined carbon, sulphuret of iron is formed on the surface; underneath a layer of graphite, and beneath that, a layer of iron with the maximum of carbon; and when grey iron containing 3.31 per cent. of graphite is melted with sulphur, white iron, containing iron 94.03, combined carbon 4.93, and no graphite, is formed. The tendency of sulphurous ores to produce white metal in their treatment in the blast furnace, has long been known; it was supposed that this was occasioned by the too great facility with which the sulphur gave to the cast iron, but ores containing large proportions of phosphoric acid will produce very grey iron, notwithstanding their fusibility, so that this explanation does not serve; these experiments above described point to the true reason. The sulphur present in the ore (if as sulphuric acid reduced in the furnace) enters into combination with the iron, displacing a corresponding proportion of carbon, which becomes concentrated in the remainder of the metal, forming white iron. To guard against this, and in order to obtain a metal which shall contain a minimum amount of sulphur, the slags should contain the maximum amount of lime, M. Berthier having shown that this earth decomposes sulphuret of iron at a high temperature, in the presence of carbon. M. Janoyer states, that the proportion of lime and silica in the slag may be as 54 to 56; it is doubtful whether such a highly basic cinder would be sufficiently fusible. Direct experiments, however, have shown that the amount of sulphur in cast-iron diminishes in proportion as the amount of lime in the slag increases. A still better flux is oxide of manganese, and it is found that when the

more iron than is required to constitute part of the burden of the furnace, may be lost, and may disappear from the crude iron. M. Jannoy believes that he has proved experimentally that the whirling of cast iron around from a height of 10 to 15 feet, in part at least, is the cause of a portion of its carbon, and its value is lost. It is the loss of sulphuret of carbon, by which the temperature of the furnace is lowered, but his experiments on this point require confirmation. The presence of a very small quantity of sulphur with very injuriously upon bar iron, an amount proportionate to the remainder of the metal "hot short," that is, incapable of being worked at a red-heat under the hammer. If the quantity of sulphur in the crude iron exceeds 0.4 per cent, it is scarcely possible to manufacture it into good wrought iron.

Silicon.—Like carbon this element enters into combination with iron in all proportions up to as high as 4 per cent. The largest quantity found by Karsten in cast-iron was 3.4 per cent, but in the above table a specimen (n) is quoted from a broken Dale containing 4.08 per cent, and we have lately found it in a sample of Nova Scotia iron as high as 5.8 per cent. Generally speaking, grey cast-iron contains more silicon than white, and the greater the quantity of graphite in the metal, the larger the amount of silicon, because the higher the temperature of the furnace, but this again will depend materially on the quality of the coal, from the use of which the silicon is probably principally derived. A clean strong coal yielding a small percentage of ash furnishes a cast-iron with less silicon than an inferior coal, the inferior burden being the same. Pig-iron smelted with hot blast contains more silicon than when the blast is cold, because of the higher temperature which prevails in the furnace, some analyses illustrating this fact have been already given. According to the experiments of MM. Jannoy and Gauthier the amount of silicon in hot blast cast-iron may be greatly influenced by varying the proportions of lime and silica in the furnace. Pig-iron obtained with a charge yielding a cinder in which the lime and alumina were to the silica as 7 to 10, had little strength, breaking readily, and analysis showed that it contained 8 per cent. of silicon. By increasing the amount of lime in the charge, so as to obtain a cinder in which the bases were to the silica as 8 to 10, and at the same time employing a blast of the highest attainable temperature, the iron produced had a much greater strength. When the proportions of lime to silica in the cinder was as 20 to 10, the iron contained only an insignificant amount of silicon, and the strength was increased in the proportions of 68 to 42. When the maximum quantity of lime was used the consumption of fuel was on the average increased to the extent of 4 per cent.

In reading the above account of the experiments of Messrs Jannoy and Gauthier, the writer of this article induced the furnace manager of the Moineaux Works to increase the yields of lime on one of his furnaces to as great an extent as in his judgment it would bear, and when the furnace was under the full influence of the excess of flux to forward him samples of the grey pig for analysis. The following results show that, contrary to the statement of MM. Jannoy and Gauthier, no advantage as regards a diminution in the amount of silicon, was hereby obtained, the proportions of that element being not perceptibly altered, though there is a slight diminution observable in the percentage of sulphur.

	Grey pig. with normal burden of lime.	Grey pig. with extra burden of lime.
Sulphur	0.067	0.048
Silicon	2.900	2.930

As the presence of silicon in pig-iron affects to a remarkable degree the yield as well as the strength of puddled bars, it is of importance that this element should be removed as effectually as possible by a refining process before the crude iron is submitted to the puddling process. Pigs with 3 per cent. of silicon give about 6 per cent. of silica, and this requires somewhere about 12 per cent. of iron to form a cinder sufficiently fluid to allow the puddled iron to become aggregated into balls, this can of course be obtained only by burning that amount of iron in the puddling furnace after the expulsion of the carbon, and while the mass is in a powdery state. This powdery mass is composed of small granules of iron mixed up with a glazy infusible cinder. The puddler turns over this mass repeatedly to expose the iron to the oxidizing influence of the furnace, the silica now taking up sufficient oxide of iron to give it fluidity begins to separate from the iron, and forms a pool at the bottom. After some time the puddler, finding the mass of cinder accumulating pretty fast, makes the first attempt to "ball up." In order to save as much iron as possible, he keeps the damper down and works the powdery mass at as low a red heat as possible. The balls, even when made, will not bear much heat under the hammer without falling to pieces, hence an imperfect weld in the hammered mass and rolled bar is the result, and although the iron may be chemically pure it is deficient in strength. By protruding the process and wasting more iron, there is no doubt but that the iron might be im-

proved, for the cinder would become richer in oxide, more fluid, and consequently offer less resistance to a perfect weld. Iron, on the contrary, with a small percentage of silicon may be "killed up" directly it is "dried," and the short time required for that operation can be conducted at the best heat of the furnace. A good welding of the mass is the consequence, in which iron is strong, and the labour of the puddler in obtaining it is much less than in the former case. Every pound of silica must have twice its weight of iron to form a cinder sufficiently rich in oxide to allow the particles of iron to become properly agglutinated. Such being the influence of silicon on both the yield and the strength of wrought iron, and such being the waste attendant on its removal in the refinery, it becomes an object of much practical importance to prevent as far as possible the formation of a silicide of iron in the blast furnace, and the observations of MM. Janoyet and Gauthier on this point require careful verification.

Manganese.—The presence of this element in pig-iron does not appear to exert much influence either for good or for bad on the quality of the metal, and even when it exists in quantity amounting to 4 or 5 per cent. in the crude iron, it disappears almost entirely during the conversion of the cast-iron into wrought or malleable. It has already been observed that the cinder from iron smelted from manganese ores contains, generally speaking, more sulphur than slags or cinders from iron ores containing no manganese. We have had numerous opportunities of confirming this, and have therefore on this account alone attached much importance to the existence of manganese in iron ores; but our attention has more recently been directed to another point which we think especially worth notice of iron manufacturers, namely, to the almost perfect removal of phosphorus from pig-iron containing a very large proportion of that element, and at the same time a high percentage of manganese. As our experiments on this important point are still in progress, we shall merely here quote a few in illustration of the purifying action we have alluded to.

Iron made from a highly phosphorised ore containing no manganese:—

	Phosphorus per cent.
Pig	3.030
Puddled bar	0.838
Drawn down bar	0.572

The finished bar was cold short in the highest degree, it was in fact nearly worthless.

Iron made from a highly phosphorised ore containing a large per-centage of manganese.

	Phosphorus	Manganese
Pig	2.60	7.20
Puddled bar	0.20	0.20
Do.	0.20	
Finished bar	0.11	

The iron was carefully watched during the puddling process. It melted very thick, and took rather more work than usual; as soon as the boiling commenced it was very violent, the metal forcing itself out of the door hole until it was checked. When it "came to nature," as the workmen term it, it worked beautifully and stood any amount of heat, in fact the heat could with difficulty be raised to the requisite degree. The yield was 22 cwt. 2 qrs. 21 lbs. of pig to produce one ton (of 20 cwt.) of puddled bar; this is about the yield of good mine iron when properly puddled. The finished bar exhibited none of the cold short quality, it was exceedingly ductile, indeed excellent horseshoes were made from it. The puddling cinder had the following composition:—

Silica	8.240
Protoxide of iron	70.490
Oxide of manganese	12.500
Phosphoric acid	7.660
Sulphur335

99715

Other observations have shown that highly manganiferous pig (without phosphorus) is puddled with difficulty, and sometimes with considerable waste, so that the advantages of an alloy of manganese would seem to be confined to those varieties of crude iron into the composition of which phosphorus largely enters.

The Conversion of Crude or Carburised Iron into Malleable Iron.—This is effected by one or more operations, which are necessarily of an oxidising nature, the object being to eliminate from the cast iron the carbon in the form of carbonic oxide gas, and the silicon, sulphur, phosphorus, and other foreign bodies in the form of oxidised

products, which pass either partially or wholly to the hearth or elsewhere. The pig-iron is either admitted to a preliminary decarburization in the refining furnace, or is "refined," and the operation is then continued in a furnace equipped for the refining of cast-iron, or "puddling furnace," or the "puddling" operation of the crude iron is effected by the operation of the puddling furnace, by the process called "puddling." It is stated (*Howe*) that, at several works abroad, the attempt is even to progress of decarburization in the puddling or boiling furnace at that point in which the conversion has proceeded only so far as to leave the iron in the state of steel, or sub-martensite, but more commonly, and that a valuable product or puddled steel, not requiring remelting in the refining furnace, is thus obtained, but this is not the case.

Fig. 1012. Method of refining.—The refining furnace is composed of a body of brick-work, about 10 feet square, rising 10 feet above the surface of the ground. The hearth, the bottom of which is of refractory gneiss placed in the position of 11 feet deep, it is 10 feet wide, being in general 2 feet by 2, with the ground sloping parallel to the face of the tuyeres, and it is made of cast iron in four plates. On the side of the tuyeres there is a single brick wall, on the three other sides there is a brick wall to prevent the external air from cooling the metal, which is always covered under an open shed or in the open air, but never in a space surrounded by walls. The chimney, from 15 to 18 feet high, is supported upon four columns of cast iron, and is placed about above the level of the hearth, in order that the labourers may work without restraint. The air is supplied by the blowing cylinders which supply the blast furnace, and enter the hearth through 6 tuyeres, so arranged that the current issuing from them on the opposite sides of the crucible are not disposed in the same place. These tuyeres, like those in the furnace in which cast iron is made, are provided with double rings, through which a current of cold water is constantly flowing and each pipe is furnished with a suitable stop valve for regulating the velocity of the blast. The tuyeres are placed, at an angle of from 25° to 30°, so as to point upon the top of the metal as it flows. The quantity of air blown into the furnace is considerable, being nearly 400 cubic feet per minute for each finery. The ground plan of a finery is shown in Fig. 1012, A being the hearth, B the tapping hole, the chill mould, and C a view of the

valves of the tuyeres. The operation of refining crude iron is conducted as follows: A fire is lit in the centre of the hearth, which is first urged by a little coke; a charge of pig-iron, about 2 tons, is then laid on, and the whole is covered up and covered with a heap of coke; the full power of the blast is then turned on, the cast iron melts, and the slag being gradually collects in the crucible, more coke being added as the first quantity burns away. The operation proceeds by itself, the melted metal is not stirred about as in some modes of refining, and the temperature is always kept high enough to preserve the metal liquid. During this stage the coals are observed continually heaving up, a movement due in part to the action of the blast, but in part to an expansion caused in the metal by the discharge of carbonic oxide gas. When all the pig-iron is collected at the bottom of the hearth, which happens in about two hours, it is blown vigorously for some time longer, the tap-hole is

opened, and the fine metal runs out with the slag into the chill mould, or pit, as it is called, which has been previously washed with a thin clay liquid, to prevent the refined metal from adhering to its surface. The chill mould is in a prolongation of the tapping hole; it is a heavy cast iron trough, about 10 feet long, 2 feet broad, and 2 to 2½ inches deep. The slag, from its inferior specific gravity, forms a crust on the surface of the metal: its separation is facilitated by throwing cold water in large quantities on the fluid mass immediately that the entire charge has left the refinery. This sudden chilling of the metal makes it exceedingly brittle, so that it can be broken into smaller pieces by heavy hammers, for the subsequent operation of puddling. The refined metal is very white, hard, and brittle, and possesses in general a fibrous radiated texture; or sometimes a cellular, including a considerable number of small spherical cavities, like a decomposed amygdaloid rock. The loss of iron in the refining process is very large, varying from 10 to 20 per cent. In the Welsh iron works, 1 ton of white iron takes from 1½ to 2 hours to refine, the consumption of coke being

from 6 to 8 cwts. and the loss about 3 cwts. Grey iron takes from 7 to 9 cwts. of coke per ton, the time required to produce being from 2½ to 3 hours, and the loss of iron per ton 4 cwt. The pig-iron is to be decarburised in the refinery, is frequently mixed with rich scrap-iron (for pig-iron), and occasionally with oxide of iron, the object being to protect the metal while in some degree from the oxidising effects of the blast, and to react on the carbon which it contains. The quantity employed depends on the degree to which the pig-iron is carburised. The crude iron, from which wrought iron of the best quality is produced, is that possessing a medium degree of carburisation, or what is generally termed grey pig-iron. White iron, which possesses an inferior degree of fluidity, is grey pig-iron, and which comes as it is termed more rapidly to nature, is that quality which is most generally employed in the manufacture of wrought iron, especially when the conversion is effected in the single operation of beating in the puddling furnace; but this species of pig-iron being the result of imperfect reaction in cooling, is always more impure than grey iron obtained from the same materials, and does not produce wrought iron of the best quality.

The coke employed in the refinery should be as free as possible from shale, and should contain only a low percentage of ash; it should especially be free from sulphuret of iron, which it often contains in considerable quantity, as it is found that nearly the whole of this sulphuret enters into combination with the metal, and does not pass off in the slag.

Refineries are sometimes worked on hot fluid iron, run direct from the hearth of the blast furnace, a considerable saving, both of time and fuel, being thereby effected. Various proposals have been patented for the employment of fluxes to assist in the removal of the impurities of pig-iron, both in the refining and puddling furnaces. Thus Mr. Hampton patented, in 1855, a flux, prepared by mixing quick lime with the carbonate of an alkali, or alkaline salt. MM. Du Maty and Fontaine proposed, in a patent secured in 1854, to purify and decarbonise iron in the refining and puddling furnaces, by the employment of fluxes prepared from the scoria of the puddling furnace, from oxide of iron and silicates or carbonates of alkalies, or other bases. Mr. Pope (1856) proposes to add the residue obtained by the distillation of kerosene or Torbane mineral, to such flux as is employed in the refining of iron. Mr. Sanderson, of Sheffield (1855), employed for the refining of iron such substances as sulphate of iron, capable of disengaging oxygen or other elements, which will act upon the silicium, aluminium, &c., contained in the metal. These and various other schemes have been suggested with the object of lessening the enormous waste which pig-iron undergoes on its passage through the refinery, for as the process is at present conducted, the partial elimination of the carbon, sulphur, phosphorus, &c., is only effected at the expense of a large quantity of iron, which is oxidised by the blast, and passes in the form of silicate into the slag; the desideratum is the discovery of some method of reducing the waste of iron, and substituting for it some other base, which will form with iron a sufficiently fusible silicate. Mr. Blackwell's proposal is that the decarburisation of pig-iron might be effected by melting it in a cupola furnace, either alone, or with minerals containing nearly pure oxide of iron; the oxide of iron would be reduced by the carbon of the pig-iron, while the silicates of the steel, with the silica, alumina, and other easily fusible alloys eliminated from the crude iron, would be separated in the form of fusible earthy glass. The employment of steam as a purifying agent for crude iron has been patented by several persons. Mr. Naumyth in 1854 obtained a patent for the treatment of iron in the puddling furnace with a current of steam, which being introduced into the lower part of the iron, passes upwards, and meeting with the highly heated metal undergoes decomposition, both elements acting as purifying agents. The steam employed is at a pressure of about 5 pounds per square inch, and passes into the metal through a species of blow-rabbit, the workman moving this about in the fused metal until the mass begins to thicken, which occurs in from five to eight minutes after the introduction of the steam; the steam pipe is then removed and the puddling finished as usual.

The advantages are said to consist in the time saved at each heat or puddling operation (from ten to fifteen minutes); the very effective purification of the metal; and the possibility of treating highly carbonised pig-iron at once in the puddling furnace, the preliminary refining being thus avoided. In October 1855, Mr. Bessemer patented a somewhat similar process for the conversion of iron into steel, the steam highly heated, or a mixture of air and steam, being forced through the liquid iron run from the furnace into a kille pot, steam being used only at an early stage of the process, and the treatment finished with heated air. In the early part of the same year Mr. Martien of New Jersey obtained a patent for a partial purification of crude iron, by causing air or steam to pass up through the liquid metal, as it flows along gutters from the top hole of the furnace or finery forge; and he subsequently proposed to include with the air or steam, other purifying agents, such as chlorine, hydrogen, and coal gas, oxides of manganese, and zinc, &c. Other methods of treating crude iron with air and

steam were made the subjects of patents by Mr. Bessemer in December 1856 and January 1857. In October a patent for the employment of steam in admixing with molten iron the smelting furnace and flaring flange, was obtained by Messrs. Armstrong and Co. of Leeds, and in August a patent was obtained by Mr. George Parry, of the Elbow Vale Iron Works, for the purification of iron by means of highly heated steam. The fluid iron is allowed to run into a reverberatory furnace previously heated, and the steam is made to impinge upon it from several tuyeres or to pass through the metal. Steel is to be obtained by treating highly carburized iron with the steam, and then running it to water, and flaring it with the addition of purifying agents, or adding to it in the furnace a small quantity of clay, and afterwards about 1 or 15 per cent. of calcium spathose ore. Mr. Parry observing that when steam was sent through the molten iron, as in Mr. Nasmyth's process, the iron quickly oxidized, covered the lower of the furnace with a high degree of heat in the furnace by raising the steam pipe a couple of inches above the surface of the metal, so that it might be exposed to the intensely heated atmosphere of the furnace, and a small opening the jet at an angle of 45°, so as to give the molten mass a motion round the furnace while the pipe was maintained in the same position at a little distance beyond the centre; when this was done, in a few minutes the iron began to boil violently, the rotatory motion of the fluid being every part of it successively into contact with the highly heated atmosphere of steam and atmospheric air, and no oxidation taking place. Having thus ascertained the proper way of using steam as a refining agent, it occurred to Mr. Parry that, as the presence of silicon in the pigs for puddling affects in a remarkable degree the yield of iron, as well as its strength, it is a matter of consequence that this element should be removed as completely as possible previous to the puddling operation; the casting of the iron would probably therefore be more profitably applied in the refinery than in the puddling furnace. Pig iron containing 3 per cent. of silicon gives 6 per cent. of silica, which, to form a fluid sufficiently fluid to allow the balling up of the iron, would require from 10 to 12 per cent. of iron; and this case, if true, only be obtained by burning that amount of iron in the puddling furnace, after the expulsion of the carbon, and while the mass is in a powdery state. The superheated steam is injected on the surface of the iron in the refinery by water tuyeres, similar to those used for hot blast at smelting furnaces; they are inclined at an angle of about 45°, and are inserted at each side of the door of the furnace, and are pointed so as to cross each other, and give the iron a circulating motion in the furnace. The tuyeres are from 3 to 4 inches in diameter, a little oxide of iron or a little in a state of fusion on the surface of the iron accelerates the action, as in common refineries, and increases the yield of metal, but to a much greater extent than when blasts of air are used. The steam having been turned on, the mass of iron commences circulating around the inclined tuyeres, and soon begins to boil, and the action is kept uniform by regulating the flow of the steam. The most impure oxides of iron may be used in the process, such as tap cinder or hammer slag from puddling furnaces, without injury to the quality of the refined metal made; the large quantities of sulphur and phosphorus which they contain being effectually removed by the detergent action of the heated steam. When 4 cwt. of cinders are used to the ton of pig, 20 cwt. of metal may be drawn, the impurities in the pig being replaced by refined iron from the cinders.

We have had several opportunities of witnessing this beautiful refining process at the Elbow Vale Iron Works, and have made the following analysis of the cinders and metal which fully bear out the above statements:—

	Pig iron,	Refined metal,
Graphite	2.40	0.70
Silicon	2.68	0.72
Slag	0.65	0.10
Sulphur	0.22	0.14
Phosphorus	0.13	0.09
Manganese	0.26	0.24
	Large cinders thrown into the refinery.	Cinder run out of the refinery.
Sulphur	1.34	0.16
Phosphoric acid	2.06	0.120

A ton of grey iron may be refined by steam in half an hour, using seven jets of steam of an inch in diameter, and with a pressure of from 30 to 40 lbs.; the temperature of the steam being from 600° to 700° F., the orifices of the tuyeres being 2 or 3 inches above the surface of the iron. As the fluidity of the metal depends upon the heat which it is receiving from the combustion of the fuel in the grate, and not on any generated in it by the action of the steam, it is evident that the supply of the latter in a given time must not exceed a certain limit, or the temperature of the fluid iron will become reduced below that of the furnace. This however partly regulates itself,

and does not require much nicety in the management, for, if too much steam be given, the ebullition becomes so violent, as to cause the cinders to flow over the bridges, giving notice to the refiner to slack his blast. The "forge cinders" used in the steam refinery contain 66 per cent. of iron; the "run out" cinder contains only 26; 40 per cent. of iron, or thereabouts, have therefore been converted into refined metal, and the resulting cinder is as pure as the ordinary Welsh mine, with its yield of 25 per cent. of iron. The following is the result of one week's work of the steam refinery:—

		cwt.	qrs.	lbs.
Pigs used	- - - - -	396	0	15
Metal made	- - - - -	393	3	1
Loss	- - - - -	2	1	14
Yield	- - - - -	20	0	14

The quantity of cinder (puddling) used was $3\frac{1}{2}$ cwt. per ton of pig. When $1\frac{1}{2}$ cwt. of cinders were used to 1 ton of pig, the yield was invariably 20 cwt. over a make of about 100 tons.

Refining by gas (German method).—The most simple form of gas reverberatory furnace is that known as Eck's furnace, which is employed at the government works of Gleiwitz and Königshütte, for refining iron made on the spot. The following description and plan of this furnace is extracted from a report to the secretary of state for war, from the superintendent of the Royal Gun factories, Colonel Wilmot, R.F.A., and the chemist of the War Department, Professor Abel.

The gas generator (which replaces the fire-place of the ordinary reverberatory furnace) is an oblong chamber, the width of which is 3 feet 9 inches, and the height from the sole to the commencement of the sloping bridge 6 feet 4 inches. It tapers slightly towards the top, so as to facilitate the descent of the fuel, which is introduced through a lateral opening near the top of the generator. Its cubical contents are about 44 feet.

The air necessary for the production of the gas is supplied by a feeble blast, and enters the generator from the two openings or tuyères of a long air chest of iron plate (figs. 1013, 1014, 1015) fixed at the back of the chamber, near the bottom. The space between the air chest and the sole of the chambers serves as a receptacle for the slag and ash from the fuel. There are openings on the other side of the chamber, opposite the tuyères, which are generally closed by iron plugs, but are required when the tuyères have to be cleaned out. There is an opening below the air-chest, through which fire is introduced into the chamber, when the furnace is set to work, and which is then bricked up, until at the expiration of about 14 days it becomes necessary to let the fire die out, when the slag and ash which have accumulated on the sole of the chamber are removed through this opening.

The hearth of the furnace is constructed of a somewhat loamy sand; its general thickness is about 6 inches, its form is that of a shallow dish, with a slight incline towards the top hole, the iron is prevented from penetrating through the hearth by the rapid circulation of cold air below the fire-bridge and the plate of the hearth.

Figs. 1016 and 1017, represent the upper oblong air-chest provided with a series of tuyères, which enter the top of the furnace just over the fire-bridge at an angle of 30°. The air forced into the furnace through these tuyères serves to inflame and burn the gases rushing out of the generator, and the direction of the blast throws the resulting flame down upon the metal on the hearth, in front of the bridge. This air-chest communicates, like the other one, by pipes, with the air accumulator of the neighbouring blast furnace. The amount of pressure employed is about 4 lbs.; but the supply of air, both to the generator and the inflammable gases, admits of accurate regulation by means of valves in the connecting pipes. There is an opening in the arch at both sides of the furnace, not far from the bridge, into which, at a certain stage of the operations tuyères are introduced (being placed at an angle of 25°) also connected with the blast apparatus and provided with regulating valves.

The refining process is conducted as follows:—The hearth of the furnace having been constructed or repaired, a brick coal-fire is kindled in the generator, through the opening at the bottom, which is afterwards bricked up. About 20 cubic feet of

cells are then lowered from above, and the necessary supply of air admitted to the furnace through the lower air chest. When these cells have been thoroughly heated, the generator is filled with iron, and a very abundant supply of air admitted through the tuyeres below (for the generation of the gas), and those over the bridge,

(for its combustion,) until the furnace is dried, when the supply of air at both places is increased, so as to raise the hearth to the temperature necessary for baking it thoroughly, upon which, about 40 cwt. of iron are introduced; the metal being distributed over the whole hearth as uniformly as possible, and the size of the pieces

being selected with the view to expose as much surface as possible to the flame. The fusion of the charge of metal is effected in about three hours, the coal used amounting to about 3½ cubic feet per hour. The gas generator is always kept filled

with coal, and the supply of air admitted from below is diminished by a regulation of the valve, whenever fresh coal is supplied, as the latter, at first, always yields gas more freely. The arrangement of the upper row of tuyères effects the combustion

of gas just as they pass from the generator on to the hearth. The hottest portion of the furnace is of course near the fire-brick, i.e. where the blast first meets with the iron. During the melting process the iron is stirred occasionally, so that the colder portion near the fire may in its turn become melted without loss of time. When the iron is ascertained to be thoroughly fused, about 3 lbs. of crushed limestone are thrown over its surface for the purpose of converting the dross which has separated into fusible slag. The two side tuyeres are now introduced into the furnace through the openings above alluded to, the width of the nozzle employed depending upon the power of the blast used. The air rushing from these tuyeres imparts with violence upon the iron, and the two currents meeting an eddying motion is imparted to the fused metal. In a short time the motion produced in the mass is considerable; the permanent slag is blown aside by the blast, and the surface of the iron thus exposed undergoes refinement, while it changes continually, the temperature of the whole mass being raised to a full white heat, by the action of the air. The iron is stirred continually, in order to insure a proper change in the metal exposed to the action of the blast. A shovelful of limestone is occasionally thrown in (the total quantity used being about 1 per cent. of the crude-iron employed). The slag produced is exceedingly fusible, and is allowed to remain in the furnace until the metal is tapped, and on cooling it separates from it completely.

The duration of the treatment in this furnace after the metal is fused, varies from two hours and a half to five hours, according to the product to be obtained. For the preparation of perfectly white iron, the treatment is carried on for five hours. A sample is tapped to examine its appearance, when it is believed to be sufficiently treated.

When the charge is to be withdrawn from the furnace, the side tuyere nearest the tap-hole is withdrawn, so that the blast from the opposite tuyere may turn the metal towards the hole. The final iron, as it flows from the tap-hole is fully white hot, and perfectly limpid; it chills, however, very rapidly, and when solidifies. A few pans of water are thrown upon those portions of the metal which are not covered with the slag, which flows out of the furnace, the object being to cool it rapidly, and thus prevent the oxidation of any quantity of iron. The loss of metal during the treatment is said not to exceed 5 per cent.

With regard to the purification which the iron undergoes in the gas reverberatory furnace, it appears to be confined chiefly to the elimination of carbon and silicon, the amount of sulphur and phosphorus undergoing but little variation, as appears from the following analysis (1867).—

	Pig iron.	Refined iron.
Silicium . . .	4.66	0.62
Phosphorus . .	0.56	0.30
Sulphur . . .	0.04	0.03

Nevertheless the iron thus refined is highly esteemed for all castings which are required to possess unusual powers of resistance; some experiments made to ascertain the comparative strain borne by the refined metal, and the same metal as obtained from the blast furnace, showed the strength of the former to be greater by one half than that of the latter.

The operation of puddling.—In the year 1783 and 1784, Mr. Henry Cort of Gosport obtained two patents, one for the puddling, and the other for the rolling of iron, “discoveries,” says Mr. Scrivenor, “of so much importance in the manufacture, that it must be considered the era from which we may date the present extensive and flourishing state of the iron trade of this country.”

The object of Mr. Cort's processes was to convert into malleable iron, cast or pig iron, by means of the flame of pit-coal in a common air furnace, and to form the result into bar by the use of rollers in the place of hammers. The process was managed in the following manner:—“The pigs of cast iron produced by the smelting furnace are broken into pieces, and are mixed in such proportions according to the degree of carbonisation, that the result of the whole shall be a grey metal. The mixture is then speedily run into a blast furnace, where it remains a sufficient time to allow the greater part of the scoria to rise to the surface. The furnace is now tapped, and the metal runs into moulds of sand, by which it is formed into pigs, about half the size of those which are broken into pieces. A common reverberatory furnace heated by coal is now charged with about $2\frac{1}{2}$ cwt. of the half refined grey iron. In a little more than half an hour, the metal will be found to be nearly melted; at this period the flame is turned off, a little water is sprinkled over it, and a workman, by introducing an iron bar through a hole in the side of the furnace, begins to stir the half fluid mass, and divide it into small pieces. In the course of about 30 minutes from the commencement of the process, the iron will have been reduced by constant

stirring to the coarseness of small gravel, and will be considerably cooled. The flame is then turned on again, the workmen continuing to stir the metal, and in three minutes' time the work is again begun, and finally, when the flame is then turned off. The hottest part of the iron now begins to leave and swell, and emit a deep lambent blue flame, which appearance is called *fermentation*; the heaving motion and accompanying flame soon spread over the whole, and the heat of the metal seems to be further increased than it was for the next quarter of an hour; after this period the temperature again falls, the blue flame is less vigorous, and in a little more than a quarter of an hour the metal is cooled to a dull red, and the jets of flame are rare and faint. During the whole of the fermentation the stirring is continued, by which the iron is at length brought to the consistency of sand; it also approaches nearer to the malleable state, and in consequence adheres less than at first to the tool with which it is stirred. During the next half hour the flame is turned off and on several times, a stronger fermentation takes place, the lambent flame becomes of a clearer and lighter blue; the metal begins to clot, and becomes much less fusible and more tenacious than at first. The fermentation then, by degrees, subsides; the emission of blue flame nearly ceases; the iron is gathered into lumps and beaten with a heavy-headed tool. Finally, the tools are withdrawn, the apertures through which they were worked are closed, and the flame is again turned on in full force for six or eight minutes. The pieces being thus brought to a high welding heat are withdrawn and shingled; after this they are again heated and passed through grooved rollers, by which the bars are separated, and the bars thus forcibly compressed acquire a high degree of tenacity. But this mode of refining did not produce altogether the desired result. It was irregular; sometimes the loss of iron was small, but at others it was very considerable, and there were great variations in the quality of the iron, as well as in the quantity of fuel consumed. These difficulties were, however, removed by the introduction of the coke furnace by the late Mr. Samuel Homfray, of Penydarren, upon which the puddling and balling furnaces came immediately into general use, with the addition of rollers in lieu of hammers.

Mr. Cort's first patent, which is for "rolling," is dated 17th January, 1783; his second, that for "puddling," is dated 18th February, 1784. It has been attempted, though we think very unjustly, to detract from Cort's merits as an original inventor, by referring to the patents of John Payne, and Peter Onions, dated respectively 21st November, 1788, and 7th May, 1783. The first was to a certain extent, undoubtedly, a patent for "rolling;" for the bars rendered malleable by a process indicated, are "*in press between the large metall rollers which have proper notches or furrows upon their surface.*" but there is no proof that any practical use was made of Payne's process, while that of Cort was almost immediately and universally adopted. It may be true therefore that Cort was the *discoverer* and not the actual *discoverer* of the process of rolling, but this in no way detracts from his merit, inasmuch as by his improvements, he was enabled to make available that which was previously useless. The same observation applies to the patent of Onions, which to a certain extent anticipated that of Cort for puddling. Onions employed two furnaces—a common smelting furnace, and a furnace of stone and brick, bound with iron work and well annealed, into which the fluid metal was received from the smelting furnace. When the liquid metal had been introduced into the second furnace by an aperture, it was closed up and subjected to the heat of fuel and blast from below, until the metal became less fluid, and thickened into a kind of paste; this the workman by opening a door turns and stirs with a bar of iron, and then closes the aperture again, after which blast and fire is applied until there is a *ferment* in the metal; the adherent particles of iron are collected into a mass, reheated to a white heat, and forged into malleable iron. That the process of puddling is here indicated there can be no doubt, but the actual operation was impracticable until Henry Cort invented the *furnace* in which it could be conducted.

Neither Mr. Cort nor his family appear to have derived much advantage from his important discoveries—discoveries which changed us at once from dependent importers of iron into vast exporters to every country of the world, and which may be considered to have founded the iron industry of Great Britain. So long ago as 1811, the chief representatives of the trade assembled at Gloucester unanimously acknowledged their indebtedness to Mr. Cort for the improvements of which he was the author, and this acknowledgment has been repeated within the last twelve months by Robert Stephenson, Fairbairn, Maudslay and Field, Cubitt, Rendel, Sir Charles Fox, Bidder, Cramphay, Hilly, and many others. In working out his inventions, Cort is said to have expended a fortune of 20,000*l.* and when his patents were completed, the leading iron masters of the country contracted to pay him 10*l.* a ton for their use, so that he would not only have been repaid, but munificently rewarded, had he not unfortunately connected himself with a man named Adam Sedgwick, chief clerk of the Navy Pay Office, who

proving to be a defective, unimproved machine, having previously destroyed the pattern and the agreement with the inventor, belonging to his partner, Henry Cort. Upon the death of Bessemer, the property, stock, and money effects of Cort went with the property passed over to the Navy Pay Office, and the unfortunate man was thus completely ruined.

The position of the furnace is of the most ordinary form. It is built generally with iron, as represented in the side view, *fig. 1004*, by means of horizontal and vertical bars,

with any joints, rivets, and kind of welds, to prevent them from starting under. Very frequently, indeed, the reverse rivet formers are affixed with cast iron plates over their whole surface. These are retained by upright bars of cast iron applied to the side walls, and by horizontal bars of iron placed across the work at right. The furnace itself is divided internally into three parts; the hearth, the bridge, and the flue. The hearth varies from 14 to 44 feet long by from 2 feet 6 inches to 3 feet 4 inches wide. The door way, by which the coke is charged, is 8 inches square, and is levelled off towards the outside of the furnace. This opening consists entirely of cast iron, and has a quantity of cast-iron rivets in it. The bars of the fire grate are movable, to admit of more readily clearing down the flue.

Fig. 1005 is a longitudinal section referring to the elevation, *fig. 1004*, and *fig. 1006*

is a ground plan. When the furnace is a single one, a square hole is left in the side of the fireplace opposite to the door, through which the rakes are introduced, in order to be heated.

a is the fire-door; *b*, the grate; *c*, the fire-bridge; *d, d*, cast iron hearth-plates, resting upon cast iron beams *e, e*, which are bolted upon both sides to the cast iron binding plates of the furnace; *f* is the hearth covered with sand; *g*, is the main working door, which may be opened and shut by means of a lever *g'*, and chain to move it up and down. In this large door there is a hole 8 inches square, through which the iron may be worked with the paddles or rakes; it may also be closed airtight. There is a second working door *h*, near the flue, for introducing the cast iron.

on that it may soften slowly, till it be ready for drawing towards the bridge. *c*, is the chimney, from 30 to 50 feet high, which receives commonly the flues of two furnaces, each provided with a damper plate or register. *Fig. 1022*, shows the main damper for the top of the chimney, which may be opened or shut to any extent, by means of the lever and chain. *A*, *Fig. 1023*, is the tap or flow hole for running off the slag or cinder.

The sole is sometimes made of bricks, sometimes of cast iron. In the first case it is composed of fire-bricks set on edge, forming a species of flat vault. It rests immediately on a bed of brickwork either solid or arched below. When it is made of cast iron, which is now beginning to be the general practice, it may be made either of one piece or of several. It is commonly in a single piece, which, however, causes the inconvenience of restraining the furnace entirely when the sole is to be changed. In this case it is a little hollow, as is shown in the preceding vertical section; but if it consists of several pieces, it is usually made flat.

The hearths of cast iron rest upon hot iron pillars, to the number of four or five; which are supported on pillars of cast iron placed on large blocks of stone. Such an arrangement is shown in the furnace, where the square pillars, *Fig. 1023*, for heating the rakes, &c., may be observed. The length of the hearth is usually 6 feet; and its breadth at the fire end part is another. Its greatest breadth, which is opposite the door, is 4 feet. In the furnace, where the horizontal plan is given above, and which produces good results, the sole exists in this part a species of ear, which opens into the mouth of the door. At its origin towards the fire place, it is 2 feet 10 inches wide; from the fire it is separated, moreover, by a low wall of bricks (the fire bridge) 10 inches thick, and from 3 inches to 5 high. At the other extremity its breadth is 2 feet. The current is governed by the sides of the hearth or hearth is not symmetrical; for sometimes it makes an advancement, as is observable in the plan. At the extremity of the sole farthest from the fire, there is a low rising in the bricks of 2½ inches, called the *stop*, for preventing the metal from running out at the *flow hole* when it begins to flow. Beyond the shelf the sole terminates in an inclined plane, which leads to the *flow*, or outlet of the slag from the furnace. This *flow* is a little below the level of the sole, and is led out of the basement of the chimney. The slag is prevented from converting here, by the fire being made to pass over it, in its way to the neck or try of the chimney; and there is also a plate of cast iron near this opening, in which a constant fire is kept up to preserve the fluidity of the *slag*, and to burn the gas that escapes from the furnace, as also to quicken the draught, and to keep the furnace end of the furnace warm. On the top of this iron plate, and at the bottom of the inclined plane, the cinder accumulates in a small cavity, whence it afterwards flows away; whenever it tends to congeal, the workman must clear it out with his rake.

The door is a cast iron frame filled up inside with fire-bricks; through a small hole in the bottom the workmen can observe the state of the furnace. This hole is at other times shut with a stopper. The chimney has an area of from 14 to 16 inches.

The *hearth* stands 3 feet above the ground. Its arched roof, only one brick thick, is raised 2 feet above the fire bridge, and above the level of the sole, taken at the middle of the furnace. At its extreme point near the chimney, its elevation is only 1 foot 6 inches, and the same height is given to the opening of the chimney. The sole is covered with a layer of finely powdered cinders from previous workings mixed with mill cinders; formerly the bottom was of sand, by which great loss of iron was occasioned, and the metal obtained of inferior quality.

The fine metal obtained by the coke is produced by a continuous operation, which calls for much care and skill on the part of the workmen. To charge the melting furnace, pieces of the wood are successively introduced with a shovel, and laid one over another on the sides of the hearth, in the form of piles rising to the roof; the middle being left open for pushing the metal, as it is successively fused. Indeed, the whole are kept as far separate as possible, to give free circulation to the air round the piles. The working down of the furnace is now closed, fuel is laid on the grate, and the mouth of the fireplace, as well as the side opening of the grate, are both filled up with coal, at the same time that the damper is entirely opened.

The fine metal in about twenty minutes comes to a white-red heat, and its thin edged fragments begin to melt and fall in drops on the sole of the furnace. At this period the workman opens the small hole of the furnace door, detaches with a rake the pieces of fine metal that began to melt, tries to expose new surfaces to the action of the heat, and in order to prevent the metal from running together as it softens, he

removes it from the vicinity of the fire-beds. When the work of the blast furnace has thus proceeded to a great extent, he must lower the temperature of the furnace to permit a final heating of the coal. He then works about with his pig-iron, the latter metal which serves as a substitute for a kind of thermometer, measured by the diameter of the hole in the bottom with a long piece of hot iron wire, as fire. The metal becomes dark by the heat and the facility of its being raised up, is the measure of the work done. It is judged to be the temperature of the furnace, and the diameter of the hole is the measure of the work done. The work is continued until the furnace is judged to be the whole charge is reduced to the state of liquid metal, the engine is then progressively stopped. With the progress of the furnace, the particles of metal begin to crystallize, the charge becomes more difficult to raise, or, in the language of the furnace, it works heavy. The raising is now finished, and nothing remains but to push the iron into the ladle. The pushing is done by pushing a long rod of metal into a furnace and make it roll about in the center of the furnace, so as to collect some metal, and form a ball of about 60 or 70 lbs. weight. With a kind of rod called a "pusher," a plug, and which he has a beard, the workman is then pushed out of the furnace and exposed to the action of the heat in order to make an artificial furnace, which he then carries to the furnace to form the furnace. When the iron is finished, the work of the furnace is over, and will be the first to raise the iron to raise, and so finish the work. Each ball is then lifted out with the tongs, if round, and is to be used as a plug, or with an iron rod worked to the top as a handle, if the hammer is to be employed, as in Staffordshire. It is usual to produce a final charge when the portion under operation has arrived at the proper condition; when this is done, the engine is stopped, and the furnace is finished.

The charge for each operation is from 4 to 5 cwt. of refined metal and 10 to 15 cwt. of fuel, which are introduced into the furnace. The iron of the furnace is very variable, according to the degree of heat in the furnace, which by consequence may suffer a considerable loss of iron in the furnace, or to the loss of the furnace and ruin the bottom. Taking the average of 85 furnace for 24 years' working, Mr. Thomas has the consumption of refined metal to produce one ton of puddle bars to be 21 cwt. 1 qr. 20 lbs. The consumption of coal is also very variable. With coal of good quality, and suitable for revolutionary furnace, the ton of puddle bars is produced with a consumption of from 12 to 15 cwt.; but if the coal be of the anthracite character, from 18 cwt. to 1 ton will be required. About five puddling furnaces are required for the purpose of one working furnace, and one refinery. Each furnace, with good workmen, turns out about 24 tons of puddle bars weekly.

The cast iron bottom and sides of the puddling furnace are kept cool by currents of air, or, in some portions exposed to the greatest heat, by water. The sides of the charcoal fire are much esteemed for lining the bottom. When melted iron comes in mass, with the addition of oxide of iron, these sides form a bottom offering great resistance to the action of the melted metal.

Various patents have been taken out within the last four or five years for the employment of chemical agents to assist in the purification of iron in the puddling furnace; some of these have already been alluded to. One of the latest is that of M. Charles Paurat of Châtelleraud, who proposes to employ a cement composed of the following substances:—oxide of iron, 14 parts; highly aluminaous clay, 30 parts; carbonate of potash, 1 part; carbonate of soda, 1 part. The iron is to be placed with the cement in layers, and heated in the furnace in the ordinary manner. After cementation it is welded, and then drawn into bars. It is stated to become thus as soft and tough as iron made from charcoal. Schafsmuller's compound, for which a patent was secured in 1835, is said by Oeremann to furnish very satisfactory results, and where competent workmen are employed, a good furnace is said to make a heat in two hours, producing neither too much nor too little cinder in the furnace. The compound consists of common salt, 5 parts; oxide of manganese, 3 parts; fine white plastic clay, 2 parts. The pig is heated as in common operations. It is melted down by a rapid heat, the damper is closed, and the cinder and metal diligently stirred. In the meantime the above mixture, in small parcels of about half a pound, is introduced in the proportion of one per cent. of the iron employed; if, after this, the cinder does not rise, a hammer slag (rolling mill cinder) may be applied.

The "Bessemer" process.—In this operation, which was the invention of Mr. Joseph Bessemer, pig iron is converted into malleable iron without the intervention of the refinery, and without any extensive waste. It is, therefore, of great value, especially as it allows of the use of better quality of pig iron than those usually employed. The construction of the "Bessemer" furnace does not materially differ from that of the "puddling" furnace, except in the depth of the hearth, that is, in the distance from the work plate below the door to the bottom plate, which, in the former, is double, or

weary as, that of the latter. In the puddling furnace the distance between the bottom and top sillom exceeds twenty inches, while in the boiling furnace it varies from twenty to thirty. In puddling the furnace is charged with metal alone, but in boiling cinder is charged along with the metal, and the top of the furnace is much higher. The bottom of the furnace is covered with broken cinders from previous workings, or with the tap cinder from the puddling furnace, which has been subjected to a process of calcination in kilns; this material, which constitutes an admirable protection to the iron plates of the furnace, is raised by the workmen "bull dog;" its preparation was patented by Mr. Hall in 1840. It is made in the following manner: the tap cinder from the puddling furnace is placed in layers in a kiln, and so arranged that a draught shall pass through from the fire holes on one side to those on the other; the kiln is filled up to the top with broken cinders, and over the whole is laid a layer of coke; about the third or fourth day, the more porous part of the cinder begins to run out of the bottom holes, leaving in the kiln a fine rich porous substance of iron, which is the substance used for lining the boiling furnace, the final portion being rejected. In 8 or 10 hours the "bull dog" is melted by the intense heat of the furnace, covering the bottom, and filling up all the interstices in the brickwork; the heat is now somewhat lowered by diminishing the draught, and the charge of pig (from 3½ to 4½ cwt.) is introduced in fragments of a convenient and uniform size, together with 30 or 40 lbs. of water; the doors of the furnace are now closed, and all access of cold atmospheric air prevented, throwing the cinder or hammer slag round the crucible, and stopping up the work hole with a piece of coal. In about a quarter of an hour the iron begins to melt, and heat the workmen find a fine steam as to leave the whole to a state of ebullition, as regards heat. In about half an hour the iron begins to melt; it is constantly turned over, and at intervals of a few minutes cinder is thrown on the surface of the mass so as to be covered with a blue flame; it soon begins to rise; a kind of fermentation takes place beneath the surface, and the mass, at first but 2 inches high, rises to a height of 10 or 12 inches, and enters into violent ebullition. During the time that this "fermentation" is taking place, constant stirring is required to prevent the iron from settling on the bottom. The boiling lasts about a quarter of an hour; after which the cinder gradually sinks, and the iron appears in the form of porous spongy masses of irregular size, which are constantly stirred to prevent their adhering together in large lumps, to facilitate the escape of the carbon, and to separate the cinder which, when the operation has been successfully completed, flows over the bottom apparently as liquid as water. The iron is now "halled up," as in the operation of puddling. The objects as to the boiling process are: the wear and tear in the furnace which occurs in treating gray pig iron, particularly that of the more fluid description; the slowness of the operation, and the amount of manual labour which it entails to produce good results. In some works the crude iron is run directly into the boiling furnace from the blast furnace, by which much saving of coal is effected, and a product of a more uniform quality obtained; but the labour of the workman becomes more oppressive from the additional heat to which he is subjected from the close proximity of the blast furnace. Iron masters are not agreed as to the respective merits of the "boiling" and "puddling" systems; some maintain that the former is more economical than the latter, which has been "refining;" others think that boiling iron has a tendency to communicate to it the "red short" quality. According to the observations of Mr. Truran, in several works where both methods are employed, the largest quantity of iron is first passed through the refinery.

Mr. Hall, the inventor of the boiling system, in descending on the merits of his process, describes how, with the same pig, the iron may be made weak and cold short; or tough, ductile, and malleable. For the first proceed thus:—Pass the pig through the refinery, then puddle agreeably to the old plan on the sand bottom; that is, melt it as cold as possible; drop the damper quite close before the iron is all melted, dry the iron as expeditiously as may be, with a large quantity of water; and, lastly, proceed to hall in a proper number of "yeen" halls; the result will be a very inferior quality of malleable iron. On the other hand, to produce a malleable iron of very superior quality, first charge the furnace with good large pig iron, adding, if required, a sufficiency of flux, increasing or diminishing the same in proportion to the quality and nature of the pig iron used. Secondly, melt the iron to a boiling consistency. Thirdly, clear the iron thoroughly before dropping down the damper. Fourthly, keep a plentiful supply of fire upon the grate. Fifthly, regulate the draft of the furnace by the damper. Sixthly, work the iron into one mass, before it is divided into balls; when thus in balls, take the whole to the hammer as quickly as possible, after which roll the same into bars. The bars are then cut into lengths, and piled to the desired weights, are then heated in the mill furnace, welded and consolidated by passing through the rolls, and thus finished for the market. In this way, from the pig to the finished mill bar, one entire process, that of the refinery, is saved. Mr. Hall

makes that, by his process, he can obtain malleable iron of any character (providing that the ore from which the pig is made are of good quality), from the softness of lead, the hardness of steel, and further that he can exhibit different qualities to the same bar and rod being crystalline, nearly as brittle as glass, the other end equal to the best iron that can be produced for fire and tenacity, while the middle exhibits a character approximating to both; and as a further illustration of the versatility of the iron that may be made by the "puddling" process, he refers to a specimen in the Geological Museum, J. Gwynne Street, London, labeled "specimens of two and a quarter inch round iron, rod and wire, manufactured at the Newcastle Iron Works, Tipton, Staffordshire." This specimen has been called a "steelball bar," it was made from a bar two inches and a quarter in diameter, and nearly seven inches in circumference, then to a "1 1/2 inch bar," half inch thick, then at its point for the cutting, becoming with a half inch gauge, and terminating with one end and a half, without exhibiting the slightest fracture.

Mr Hall was led to the discovery of the "puddling" principle, by seeing the extremely high fires which took place in the ordinary puddling furnace owing to a high degree of heat, and the expense of the fuel of iron produced by the combustion; it occurred to him, that if such good iron could be made from cheap iron, a very superior product might be obtained from puddling iron with equally good fluxes, and the result of experiment is fully answered by experience, though for a long time he was unable to make his discovery practically useful, on account of the difficulty of getting furnace linings and capable of enduring the intense heat required and the corrosive action of the fluxes. Puddling furnaces were then made of brick and clay, which had failed. He succeeded at last by lining the interior of the furnace with iron, and protecting them with a coating of prepared tap cinders.

In America, the "puddling" and "puddling" processes are both in use; the former gives preference to the latter as being the most profitable, but it can only be employed to a limited extent for lack of coal; in a rolling mill, therefore, half

1025

the furnaces are employed for boiling, and half for puddling, the latter supplying cinder for the former. In the eastern states where the fuel is anthracite, double

puddling furnaces are employed and a blast is used, the limited supply of the variety of coal rendering it impossible to get the requisite heat by merely the draught of the chimney. Fig 1123 represents an anthracite furnace lined vertically through the grate, hearth, and chimney. It differs from the ordinary puddling furnace chiefly in the greater depth of the grate, which is made to contain from twenty to twenty-five inches of coal,

and in the lesser height of the chimney, which, as a least is employed, need only be sufficiently high to carry the hot gases out of the furnace; the letters a, a, a, a, indicate the position of the iron cross binders, which serve to hold together the

cast iron plates of the enclosure, and to prevent the sinking of the roof from the expansion and contraction of the brickwork.

The blast machines are fans, the best form of which is shown in *fig. 1029*. (*Overman*.) The wings of this fan are encased in a separate box; a wheel is thus formed, which rotates in the outer box, the figure shows a horizontal section through the axis. The wings are thus connected, and form a closed wheel, in which the air is whirled round, and thrown out at the periphery. The inner case, which revolves with the wings, is fitted as closely as possible to the outer case, at the centre wear a, a, a, a. The speed of the wings is sometimes as much as 1500 revolutions per minute. The motion of the axis is produced by means of a leather or india-rubber belt and a pulley. This variety of fan is used at the puddling furnaces at Ebbw vale, where the fuel is small coal.

Fig. 1030 is a horizontal section of the double anthracite puddling furnace. The

grate measures 3 feet by 5. The width of the furnace externally is from 5½ to 6 feet. The hearth is usually 6 feet in length. It has two work doors, one directly opposite the other. Two sets of workmen are required therefore at the same time; double the quantity of metal is charged, and the yield is twice that of a single furnace; the economy is in the room, fuel, and labour: one good puddler only being required to manage the operation. Double puddling furnaces are also used in several works in England, but as Mr. Truran observes, the economical advantages attending them in point of fuel are lost if the puddlers do not work well to time: they must bring their heats to the respective stages simultaneously, for if one is kept waiting for a short period by the other, the loss in iron more than balances the reduced consumption of coal. This difficulty of obtaining men who will work well in concert has operated against the use of the double furnace, which would otherwise certainly supersede the single, as combined with the process of running the iron in liquid from the blast furnace, the consumption of fuel is under the one half of the quantity demanded with single furnaces working cold iron.

Puddling furnaces are sometimes constructed with what is called "water boilers," the hearth is surrounded with heavy cast iron plates, in which is formed a passage of an inch or an inch and a half bore, through which a current of cold water is caused to flow, the object being to protect the furnace from the destructive action of the heat and clinker. *Overman* found such furnaces to work well with fusible metal such as is produced from a heavy burden on the blast furnace, or from ores containing phosphorus; but with iron requiring a strong heat, such as results from a light burden on the blast furnace, or when it contains impurities firmly and intimately combined, puddling furnaces with cooled boilers failed to make good malleable iron.

We do not know whether the iron manufacturers in England will assent to the following proposition laid down by the American metallurgist, viz. "That the smaller the amount of coal consumed, or the lower the temperature of the hearth in the blast furnace, the better will be the quality of the metal; that is, the more fit it will become for improvement in the puddling furnace. The advantage of heavy burden in the blast furnace, is not only that it reduces the first cost of the metal, but makes a far superior article for subsequent operations. The worst cold short, or sulphurous metal, smelted by a low heat is quite as good as the best metal from the best ore smelted by a high temperature." Whatever may be thought of the latter part of this quotation, no iron manufacturer will deny that careful attention to the blast furnace is the best security of success in the puddling furnace, and that success in the one is in proportion to the economy observed in relation to the other; or that it is hopeless to attempt to improve in the puddling furnace pig iron made in a furnace that is constantly changing its burden and management, such iron is most advantageously disposed of by being worked up into coarse bar or railroad iron.

In the autumn of 1836 the attention of iron masters and of the public generally was powerfully excited by a proposal from Mr. Bessemer to manufacture iron and steel

from cupola iron, without any fuel at all. The views of Mr. Bessemer were first announced and set forth in a paper read by that gentleman at the meeting of the British Association held at Cambridge in August, 1856, from the paper the following extracts are taken, being part of the apparatus employed, and of the process of converting.

"The furnace is a cylindrical vessel of three feet in height, somewhat like an ordinary cupola furnace, the interior of which is lined with fire bricks; and at about two inches from the bottom are inserted five tuyeres, the number of which are formed of wrought iron, the orifices of each tuyere just being a little more than three sixteenths of an inch in diameter. These are so put into the brick lining from the center so as to admit of their removal or renewal in a few minutes when they are worn out. At one side of the vessel, about half way up from the bottom, there is a hole made for passing in the crude metal, and on the opposite side a tap hole stopped with loose, by means of which the iron is run out at the end of the process. The vessel is placed above the discharge hole of the blast furnace so to allow the iron to flow along a gutter into it. A small brass cylinder is triplicated, capable of containing air at a pressure of 10 or 15 lbs. to the square inch. A communication having been made between it and the tuyeres, the converting vessel is in a condition to commence work. It remains, however, in this state, except for the first half, if not at least half, of the process. It is the latter. The tuyeres are situated nearly close to the bottom of the vessel, the fluid metal rises, therefore, some 18 inches or two feet above them. It is necessary, in order to prevent the metal from entering the tuyere holes, to turn on the blast before allowing the crude iron to run into the vessel from the blast furnace. This having been done, and the fluid iron run in, a rapid boil is up of the metal in being poured in. Within the vessel, the metal being turned violently about, and dashed from side to side, shaking the vessel by the force with which it moves from the throat of the converting vessel. Flame will then immediately issue, accompanied by a few bright sparks. This state of things will continue for about 15 or 20 minutes, during which time the oxygen of the atmospheric air combines with the carbon contained in the iron producing carbonic acid gas, and at the same time evolving a powerful heat. Now as this heat is generated in the interior of, and is dissipated in a very rapid fiery bubbles through, the whole fluid mass, the metal about the greater part of it, and its temperature becomes immensely increased, and by the expiration of 15 or 20 minutes the mechanically mixed carbon or graphite has been entirely consumed. The temperature is, however, so high that the chemically combined carbon, now known to separate from the metal, as is at once indicated by an immense increase in the volume of the flame rushing out at the throat of the vessel. The metal now rises several inches above its natural level, and a light frothy slag makes its appearance, and is thrown out in large foam-like masses. This violent eruption of steam generally lasts 5 or 6 minutes, replacing the shower of sparks and cinder which always accompanies the boil.

"The rapid union of carbon and oxygen which thus takes place, adds still further to the temperature of the metal, while the diminished quantity of carbon present, allows a part of the oxygen to combine with the iron, which undergoes combustion, and is converted into oxide, at the excessive temperature that the metal has now acquired; the oxide, as soon as it is formed, undergoes fusion, and forms a powerful solvent of those earthy bases that are associated with the iron. The violent ebullition which goes on mixes most intimately the scoria and metal, every part of which is brought into contact with the fluid, which will thus wash and cleanse the metal most thoroughly from the silica and other earthy bases, while the sulphur and other volatile matters which cling so tenaciously to iron at ordinary temperatures, are drawn off, the sulphur combining with the oxygen and forming sulphurous acid gas. The loss in weight of crude iron during its conversion into an ingot of malleable iron was found on a mean of four experiments to be 12½ per cent., to which will have to be added the loss of metal in the finishing rolls. This will make the entire loss probably not less than 18 per cent., instead of about 28 per cent., which is the loss on the present system. A large portion of that metal is, however, recoverable, by treating with carbonaceous gases the rich oxides thrown out of the furnace during the boil. These slags are found to contain innumerable small grains of metallic iron, which are mechanically held in suspension in the slags, and may be easily recovered by opening the tap hole of the converting vessel, and allowing the fluid malleable iron to flow into the iron ingot moulds placed there to receive them.

"The masses of iron thus formed will be perfectly free from any admixture of cinder, oxide, or any other extraneous matters, and will be far more pure and in a considerable state of manufacture than a pile formed of ordinary puddled bars. And thus it will be seen that by a single process, requiring no manipulation or particular skill, and with only one workman, from 3 to 5 tons of crude iron passes into the condition of

several piles of malleable iron in from 30 to 35 minutes, with the expenditure of about $\frac{1}{2}$ of the blast now used in a fluey furnace, with an equal charge of iron, and with the consumption of no other fuel than is contained in the crude iron. . . .

"One of the most important facts connected with this new system of manufacturing malleable iron, is that all the iron so prepared will be of that quality known as *charcoal iron*, because the whole of the processes being conducted without the use of mineral fuel, the iron will be free from those injurious properties which that description of fuel never fails to impart to iron that is brought under its influence.

"At that stage of the process immediately following the boil the whole of the crude iron has passed into the condition of *cast steel* of ordinary quality. By the continuation of the process the steel so produced gradually loses its small remaining portion of carbon, and passes successively from hard to soft steel, and from soft steel to *swely iron*, and eventually to very soft iron: hence at a certain period of the process any quality of metal can be obtained."

The phenomena attending this novel process of iron making are very well described in the above extract, and if we substitute for the words "a few bright sparks," the words "showers of bright sparks, poured out in enormous quantities, projected thirty or forty feet into the air, and falling on all sides in a thick shower," a good idea may be formed of the gorgeous display of pyrotechny which is exhibited. We must demur, however, to the statement that "the sulphur and other volatile matters present in the crude iron are drawn off;" the fact being that the sulphur and phosphorus appear to have retained little if any diminution, notwithstanding the excessive temperature and the powerful oxidising action to which the iron has been subjected. Thus Mr. Alsford, in a specimen of Mr. Bessemer's product from 0.4 to 0.5 per cent of phosphorus, and from 0.1 to 0.06 per cent of sulphur; the Hibernian pig, from which it was stated to have been prepared, containing 0.5 of the former and 0.06 of the latter, and in a sample, broken off from an ingot cast at Blaenau House, Sept. 1st, 1856, on which occasion we were present, and witnessed the whole process, we obtained 0.6 per cent of phosphorus and 0.08 per cent of sulphur; similar results have been obtained by other chemists. The carbon and silicon, on the other hand, are eliminated, the latter wholly so, while the quantity of the former is reduced to a few hundredths per cent; we think also that Mr. Bessemer is mistaken in stating that the iron produced by his method contains "an admixture of oxide," for the specimens which we have had an opportunity of examining presented unmistakable evidence of partial oxidation in the very centre of the ingot, nor do we see how it could well be otherwise.

It will easily be imagined that a process which, if successful, must have revolutionised the whole iron manufacture, was speedily subjected to a most careful and sifting investigation; and, for some months after its announcement, the papers were filled with communications from all parts of the country, detailing experiments made on the large scale to test its value; the results, unfortunately for the ingenious projector, were unanimously unfavourable. We quote first from the "Mining Journal" of Nov. 29, 1856.

"The Dowlais Company appear to have thoroughly and impartially tested Mr. Bessemer's process, and the results obtained can only be regarded as a total failure. . . . A Bessemer furnace was erected, and acted excellently as far as the process was concerned, but failed to produce anything like malleable iron. The iron used was from clay-ironstone, Whitehaven hematite, and small portions of forge cinders, in the proportions usually employed in Wales for rails and merchant iron. After the metal had been subjected to a blast of 8 lbs. pressure it was withdrawn and taken to the 'squeezer,' as is usual with puddled blooms, in take out the dross and unite the particles of metal. Instead of acting like puddled iron Mr. Bessemer's bloom under the squeezer was a mere mass of red-hot friable matter, and, from its crumbling and non-cohesion, was with difficulty formed into an ingot: when passed through the rolls it broke on the drawing side as easily as very 'red short' iron, to the infinite gratification of the men, who greeted each failure with hearty cheers. By mixing slag with the metal a slight improvement was effected, but, on being submittted to a similar manipulation, it was found to be no better than 'cold short' iron."

From the "Cobdenian," 10th Jan. 1857:—

"On December 31st the Briton Ferry Iron Company received two of Bessemer's finest ingots of iron to test its value after passing through the rolls. Notwithstanding every care that was bestowed on the process, it was found impossible to do anything with it to the purpose, and the manager informs us that cold short iron, after passing through the same process, is worth by at least 24 per cent more than that tried on this occasion."

At a meeting of the Polytechnic Society at Liverpool, Monday, Sept. 16, 1856, the chairman, Edward Jones Eyre, is reported ("Daily News") to have said that a

from retaining the last portion of carbon with its ordinary tenacity, and that it can only be made to yield it up by the action of a great temperature and oxygen; it then passes to the state of what is called anthracene, which is a solid, black, lustrous, vol. v. p. 3. It is said that the only variety of barrow that is free from carbon. It is stated, however, that the clearest of the ice is made by the action of the sun's rays, and it remains by proper treatment any desired quantity of carbon may be retained, and it remains to be proved how far this will be practicable on a large scale, and whether those variations of temperature and pressure in the process can really be produced.

The main driving shaft is carried at the end of a large iron wheel, which is connected to the different machines through smaller toothed wheels. (1) These three are driven by six, four of which drive four different systems of cylinders, and the two others work the hammer and the shears. The different cylinders of one work are placed on the same arbor, because they are not intended to get out of time and have to be locked according to the diameter. In order to save time and labour, care is taken to make the cylinders of one work follow the line the hammer, the shears, and the rolling cylinders, and on the other side, to place the several systems of cylinders for drawing out the iron into bars. For the same reason the rolling furnaces ought to be grouped on the side of the hammer; and the reheating furnaces on the other side of the works.

The hammers, fig. 1031, are made entirely of cast iron; they are nearly 10 feet long, and consist usually of two parts, the helve *c*, and the head or pane *d*. The latter

enters with friction into the hammer, and is retained in its place by wedges of iron or wood. The great masses of several hammers running from each other, for the purpose of giving different forms to the bar, &c. A ring of cast iron is fitted to the main-shaft, bearing movable cams *a* & *b*, which drive the hammers *d*, by lifting a wedge round its fulcrum *f*, and then letting it fall vertically. In one iron work, this ring was found to be 3 feet in diameter, 18 inches thick, and to weigh 4 tons. The weight of the belve (hammer) of the corresponding hammer was 3 tons and a half, and that of the head of the hammer a hundred weight.

The anvil consists of two parts; the one upon the point of the iron, is the counterpart of the pane of the hammer, it shows weight a hundred weight. The second, named the neck of the anvil, weighs 4 tons. It forms a parallelogram, with the edges rounded. The hammer is caught from the point of the frame, is laid and turned about upon it, by means of a rod of iron welded to each of them, called a power. Some the weight of these powers is very great, and the strokes very considerable, the utmost precautions must be taken in setting the hammer and its axle upon a substantial mass of masonry, as shown in the figure, *g* is which is built a house, or some quality of flooring of wood, formed of beams placed in transverse levers that reach under such beams, passing an axle, *h*, and *i* by partially sliding the levers, raising or lowering the axle. In some works, *g* is a set of iron bars, which is a pattern in cast iron.

Three hammers are very frequently mounted on levers of the first kind, with the centre of motion about one third or one fourth of the length of the belve from the iron wheel. The principle of this construction will be understood by inspection of fig. 1192. The short end of the lever, which is struck down by the hammer, is fixed upon the end of an elastic beam *a*, and transiently releases, causing the long end to strike a handle *h*, and upon the anvil *a*.

Fig. 1192 is the frame of a hammer; to the left of 1, is the axis of the primary

cam, 2, 3, consisting of 8 wheels, each formed of a circular bar of cast iron, which are joined together to make the cam-work wheel. 4, 5, 6, are put on the driving cam or hinge made fast by wooden wedges; *b*, *b*, are standards of the frame with *c*, *d*, *m*, is which the belve of the large hammer has its fulcrum about *u*. *k*, the side part of the frame. Another part *h* is the or vice is seen at *m*. *n* is a strong stay, to strengthen the frame work. At *r* two parallel hammers are placed, with cast-

iron heads and wooden belves. *s* is the anvil, a very massive piece of cast iron. *t* is the end of a vibrating beam, for throwing back the hammer from it forcibly by recoil. *x* *y* is the outline of the water-wheel which drives the whole. The cams or tappets are shown mounted upon the wheel *6*, *g*, *h*.

Squeezers are machines which condense a ball by pressure. They are either single or double, their construction will be readily understood from fig. 1193, which represents

a single level squeezer of the simplest construction; the bed plate *a* is cast in one piece; it is 6 feet long, 15 inches wide, and 12 inches high. The whole is screwed down on a solid foundation of stone, brick, or timber. *b* is the movable part, which

makes from 90 to 90 m. per minut. The motion is imparted by the crank *c*, which in turn is driven by means of a strap and pulley by the elementary power. The diameter of the fly wheel is from 3 to 4 ft. The anvil *d* is about two feet in length and from 12 to 14 inches in width; it is a movable plate, at least 3 inches thick, which if injured can be replaced by another; the face of the working part of the lever exactly fits the anvil, and consists of plates attached by means of screws. It is desirable to have all these face plates in small parts of 6 or 10 inches in width, by this means they are secured against breaking by expansion and contraction. The whole machine, including the crank and everything, is made of cast iron, and weighs from 4 to 5 tons. A working 100 tons the machine is both cheap and durable, and will make an 100 tons of iron per week.

Fig. 1034 represents the double squeezer, employed at many English iron works. The drawing is taken from a machine at the Dowlais Iron works, figured in Mr. Truran's work. Many other forms are in use.

Fig. 1035 represents Brown's patent bloom squeezer. The heated ball of puddled iron *x*, thrown on the top is gradually pressed between the revolving rollers as it

descends, and at last emerges at the bottom, where it is thrown on to a movable "Jacob's ladder," by which it is elevated to the rolls. This machine effects a considerable saving of time, will do the work of 12 or 14 furnaces, and may be constantly going as a feeder to one or two pairs of rolls. There are two distinct forms of this machine; in the one figured the bloom receives only two compressions; in another, which is much more effective it is squeezed four times before it leaves the rolls and falls upon the Jacob's ladder. Another form of squeezer is shown in fig. 1036.

A table *A* with a ledge rising up from it to a height of about 2 feet, so as to form an open box, is firmly imbedded in masonry; within this is a revolving box, *c*, of similar character, much smaller than the last, and placed eccentrically in regard to

11. The ball or bloom is placed between the innermost revolving bar *c* and the outer case *a* where the space between them is greatest, and is moved round all its circumference *a*, compressed and fit for the rolls.

Cylinders.—The compression between cylinders new iron, in a few seconds, that subsiding and disappearance of the fibres, which 40 years ago could not be accomplished till after many hours in the furnace, and many thousands of hammers. The cylinders may be constructed but two kinds: 1, those which serve to draw out the bar, called pulling rolls; 2, rolling mills, and which are, in fact, massive cylinders. 2, the cylinders of cast-iron, called rollers, for drawing into bars the masses iron after it has received a welding, is never so much applicable. This second kind of cylinders is subject to several variations, according to the purposes for which they are required. Their diameter may vary from 2 inches square to less than one-eighth of an inch.

Hence, the cylinders there is a heavy frame, in which the rollers and the shafts hold when the iron is compressed. The rollers of this frame, composed of cast-iron, are mounted on a body of solid masonry, capable of supporting the enormous load of the cylinders. The axis of each roller is supported by the ends of the shaft, to which cylinders may be made fast, by securing them with screws and bolts. Moving bars of cast iron are fixed in between, but never still better, not only because the uprights and bearers may be more easily fixed to them, but because the hammer out of heavy metal is more liable to chatter or capsize, an accident which happens frequently to the wooden beam. A mill of water is supplied by a pipe to each pair of cylinders, to hinder them from getting hot; as also to prevent the iron from adhering to the cylinder, by cooling its surface, and perhaps producing in it a slight degree of oxidation.

The shafts are 1 foot in diameter for the hammer and the revolving rollers, and 6 inches where they communicate motion to the cylinders designed to draw the iron into bars.

The rollers are employed either to work out the lump or ball immediately after it leaves the puddling furnace, as in the Welsh system, or only to draw out the piece, after it has been shaped under the hammer, as is practised by most of the Scotch fire establishments. These revolving cylinders are generally 7 feet long, including the trunnions, or 5 feet between the bearings, and 1 foot in diameter, and weigh in the whole from 4 to 4½ tons. They contain from 5 to 7 grooves, each of an elliptical form, one smaller than another in regular progression, as is seen in fig. 1037. The small axis of each ellipse, as formed by the union of the upper and lower grooves, is always placed in the vertical direction, and is equal to the great axis, or horizontal axis of the succeeding groove; so that in transferring the bar from one groove to another, it must receive a quarter of a revolution, whereby the iron gets elongated in every direction. Sometimes the revolving rolls serve as preparatory cylinders, in which case they bear towards one extremity regular grooves, as the figure exhibits. Several of these large grooves are bevelled with small angles, analogous to the teeth of files, for lifting the lump of iron, and preventing its sliding. On a level with the under side of the grooves of the lower cylinder, there is a plate of cast iron with notches in its edge equal to the grooves. The piece, called the apron, rests on these rods, and serves to support the ball and bars raised on the bottom of the rollers, and to receive the fragments of solid metal, which fall off during the drawing. The hammers in which the rollers are supported and revolve, are made of great strength. Their height is 5 feet; their thickness is 1 foot in the side perpendicular to the axis of the cylinders, and 10 inches in the other. Each pair of hammers is connected at their upper ends by two iron rods, on which the workmen rest their toes or pliers for passing the lump or bar from one side of the cylinders to the other.

The ends or bushes are each composed of two pieces; the one of hard iron, which presents a cylindrical notch, is framed into the other which is made of cast iron, as is clearly seen in fig. 1047.

The iron bar delivered from the square grooves, is cut by the shears into short lengths, which are collected in a bundle in order to be welded together. When this bundle of bars has become hot enough in the furnace, it is conveyed to the rollers, which differ in their arrangement according as they are meant to draw iron from a large or small piece. The first, fig. 1037, possess both elliptical and rectangular grooves; are 1 foot in diameter and 3 feet long between the bearings. The bar is not

finished under these cylinders, but is transferred to another pair, whose grooves have the dimensions proper for the bar, with a round, triangular, rectangular, or fillet form. The triangular grooves made use of for square iron, have for their profile an isosceles triangle slightly obtuse, so that the space left by the two grooves together may be a rhombus, differing little from a square, and whose smaller diagonal is vertical. When the bar is to be passed successively through several grooves of this kind, the larger or horizontal diagonal of each following groove is made equal to the smaller or upright of the preceding one, whereby the iron must be turned one-fourth round at each successive draught, and thus receive pressure in opposite directions. Indeed the bar is often turned in succession through the triangular and rectangular grooves, that its fibres may be more accurately worked together. The decrement in the capacity of the grooves follows the proportion of 15 to 11.

When it is intended to reduce the iron to a small rod, the cylinders have each a diameter, that three may be set in the same housing frame. The lower and middle cylinders are employed as roughing rollers, while the upper and middle ones are made to draw out the rod. When a rod or bar is to be drawn with a channel or gutter in its form, the grooves of the rollers are suitably formed.

To draw out square rods of a very small size, as nail-rod, a system of small rollers is employed, called *slitters*. Their ridges are sharp-edged, and enter into the opposite grooves $\frac{1}{2}$ inches deep; so that the flat bar in passing between such rollers is instantaneously divided into several strips. For this purpose the rollers represented in fig. 1038, may be put on and removed from the shaft at pleasure.

The velocity of the cylinders varies with their dimensions. In one work, cylinders for drawing out iron of from one-third to two-thirds of an inch thick, make 140 revolutions per minute; while those for iron of from two-thirds of an inch to 3 inches, make only 65. In another work, the cylinders for two inch iron, make 95 revolutions per minute; those for iron from two-thirds of an inch to an inch and a third, make 120; and those for bars from one-third to two-thirds of an inch, 150. The roughing rollers move with only one-third the velocity of the drawing cylinders.

The shingling and plate rolling mill is represented in fig. 1037. The shingling mill, for converting the blooms from the balling furnace into bars, consists of two sets of grooved cylinders, the first being called *puddling rolls* or *roughing rolls*; the second are for reducing or drawing the iron into mill-bars, and are called simply *rolls*.

a, a, a, a, are the powerful uprights or standards called *housing frames*, of cast iron, in which the gudgeons of the rolls are set to revolve; b, b, b, b, are bolt rods for hind-

[illegible]

In the cylinder drawing, the workman who holds the ball in goes first to the first of the elliptical grooves, and a second workman, on the other side of the cylinders, receives this lump and hands it over to the first, who repeats it between the rollers after turning them somewhat closer to each other by getting a turn or two adjustment screws. After the lump has passed five or six times through the same groove it has got an elliptical form, and is rolled in England a second time, passed through a second groove of less size which straightens the cylinder. In this state it is subjected to a third pair of cylinders, by which the iron is drawn into flat bars four inches broad and half an inch thick. From the ball rollers full round about the cylinders, which are afterwards added to the pulling gear. In a minute and a half the rude lump is transformed into bars with a smooth and rapidity which the experienced eye can hardly follow. A steam engine of forty horse power can rough down in a week 200 tons of iron.

This iron, called mill-bar iron, is however of too high a quality to be employed in any machinery, and it is subjected to another operation, which consists in passing several pieces together, and working them into a mass of the best quality. The iron bars, while still hot, are cut by the shears into a length proportioned to the length of the iron bar that is wanted, and four rows of these are usually laid over each other into a heap or pile which is placed in the re-heating furnace, and exposed to a free circulation of heat, one pile being set on fire while another. In a half or three quarters of an hour the iron is hot enough, and the pieces now sticking together are carried in successive piles to the bar drawing cylinders to be converted into bars, which are reckoned of middle quality. When a very tough iron is wanted, as for anchors, another welding and rolling must be given. In the re-heating operation the loss is from 8 to 10 per cent. on the large bar, and from 10 to 12 in smaller work. The consumption of coals in heating the large pile averages 7 cwt. to the ton of iron charged; in the smaller sizes 10 cwt.; and in heating the single rolled iron 15 cwt.

The re-heating furnace is shown in section in fig. 10. It differs but little from a puddling furnace. The whole interior, with the exception of the hearth, is made of

102

from 6 to 12 inch resting on fire-brick, it generally requires making after 1 or three heats. The height of the fire-brick arch, or its span, is the same as the diameter of the furnace.

of and. For the purpose of a pure sound in the coast is the better. The beach slopes considerably towards the line, the object of which is to keep the beach dry and hard. There is a wide narrow strip of sand with the idea of the wind, forming a very fine sand, which is off the beach at A, at which there is a small fire to keep the sand liquid. The beach is of the same kind.

bottom is from 8 to 12 inches. The area of the fire place averages 12 feet, and the width of the furnace varies from 4 to 8 feet. When the gases are completely consumed the door is shut, and the heat is directed around the charge, a small quantity of air, the temperature raised to the highest intensity as quickly as possible, and the workmen turn the pieces over from time to time that they may be brought to a uniform welding heat in the shortest possible time.

It is thought by many that a purer iron is obtained by subjecting the bars so they come out of the puddling furnace to the action of the hammer at first rather than to the working rollers, as by the latter process various impurities remain in the metal, which the hammer expels. Hence in some works the balls are first worked under the large hammer, and then the slabs are being afterwards heated in the form of pieces of rods, pushed over each other, are passed through the roughing mill.

Bars intended for boiler or tin plates are made from the best and best quality iron. The raw pig is refined in the usual manner with coke, the fine amounting to from 1½ to 3 cwt. per ton. It is then refined a second time with charcoal the fine amounting again to from 1½ to 3 cwt. per ton. After this second refining the bars are rolled into flat plates white hot by the tilt hammer and then washed with water, the scale coming in at it more easily broken into small scales. The slabs are pushed into a furnace and welded in the hollow fire, each being the full; the slabs are laid across the fire, and do not come into contact with the fuel; the blast is thrown under the fuel, and the heat is increased, when the plates are nearly at the forging point, they are withdrawn and passed under the rollers; they are again heated in the hollow fire, then rolled and heated a third time in the ordinary reverberatory furnace, after which they are drawn out into flat bars for boiler plates, or for the plates for tin. These plates amount to from 3 to 4 wt. per ton. About 9 hours are employed in 12 hours, each heat amounting to ½ cwt. of refined metal, and consuming 3 baskets of charcoal.

The bars intended for tin plates are repeatedly heated and rolled until of the required thickness, the plates are then cut into squares, and annealed by exposing them the several hours to heat in covered iron boxes, being allowed to cool very slowly, this gives the plates the proper degree of pliancy. The next operation is that of pickling; the plates are immersed in dilute sulphuric acid for the purpose of removing from their surface all oxide and dirt; after remaining in it a while for the requisite time, they are thoroughly washed in successive troughs of water, and then dried in saw dust, finally the surfaces of the metal are prepared for the reception of the tin, by rubbing them with leather upon cushions of sheepskin. The spent sulphuric acid is run out into evaporating pans, and the sulphate of iron crystallized out. In order to tin the plates, they are immersed in a bath of molten tin, the surface of which is covered with tallow or plum oil; when sufficiently covered, they are transferred to the *brocher* in the left hand side of the trough; he passes a rough brush rapidly over each side of the plate, whereby the superfluous tin is removed. He then passes the plate again into the tin bath, and passes it out in his left hand, the *brocher*, who gives it a washing. The plate passes through several hands, being dried. Great skill is required in the tinning process; nevertheless in a well conducted work the wastage does not amount to more than 10 per cent.; a small percentage of which are washed as to require to be reworked. Great care is taken to avoid waste, the being worth 150*l*. per ton. A box of 225 sheets of tin plates 10 inches by 14 inches contains about ½ lb. of tin. See TIN PLATE.

The processes pursued in the smelting works of the Continent have frequently been viewed to obtain from the ore malleable iron directly, in a pure or nearly pure state. The furnaces used for this purpose are of two kinds, called in French, 1. *Four à l'acier*, or *Forges Catalanes*; and 2. *Fourneau àacier*, or *Forges Allemandes*.

In the Catalan, or French method, the ore previously roasted in a kiln is afterwards strongly torrefied in the forge before the smelting begins; operation which is accomplished in succession. ores treated in this way should be very fusible and very rich, such as black sands of iron, hematites, and certain spathose ores. From these parts of ore, 50 of metallic iron have been procured, but the average product is 10. The furnaces employed are rectangular hearths, *figs* 1040 and 1041, the water-lifting machine being employed to give the blast. See METALLURGY. There are three varieties of this forge; the Catalan, the Navarrese, and the Hungarian. The dimensions of the first, the one most generally employed, are as follows: 21 inches long in the direction *p. p.*, 1041; 18½ broad, at the bottom of the hearth or crucible, in the direction *p. p.*, 1042. The tuyere, *q. p.*, is placed 2½ inches above the bottom, so that its axis is directed towards the opposite side, about 2 inches above the bottom. But it must be movable, as its inclination needs to be changed, according to the stage of the operation, or the quantity of the ore. It is then raised or lowered with poles of clay; and even with a graduated circle, for the workmen make a great many of

this matter. The hearth is lined with a layer of *lutite* (clay) and charcoal dust work together, and the ore after roasting is added; the small powder being set aside to be used in the course of the operation. The tuyere is placed on the left opposite to the blast in a sharp saddle ridge, and it occupies one-third of the furnace. In the remaining space of two-thirds, the charcoal is put. To supply the small ore in the hearth, it is covered with *manne* (clay) mixed with clay.

The fire is urged with more force during the first two hours, the workmen being constantly employed in pushing down more charcoal as the former is going lower away, so as to keep the space full, and prevent the ore from crumbling down. By a blast so tempered at the beginning, the ore gets well calcined, and partially reduced in the way of cementation. But after two hours, the full force of the air is given; at which period the furnace ought to be cooled. It is easy to see whether the temperature be sufficiently advanced, by the aspect of the flame, as well as of the ore, which becomes spongy or cavernous; and the workmen now resume the furnace by detaching the pieces of iron from the bottom, and placing them in front of the tuyere. When the fire ceases are afterwards the workmen upon the top, they must be watched, to prevent their being blown away, and to keep them evenly spread over the whole surface of the light fuel. They increase the quantity of the products, and give a proper facility to the scoria. When the scoria are void, the quantity of charcoal must be diminished; but if then, they must be increased. The vacuum of air is allowed to run off by the charcoal hole. The process lasts from five to six hours, after which the party must be taken out, and placed under a hammer to be cut into lumps, which are afterwards forged into bars.

Each mass presents a mixed variety of iron and steel; in proportions which may be modified at pleasure; for by using much of the charcoal, and making the tuyere dip towards the sole of the hearth, iron is the chief product; but if the operation be conducted slowly, with a small quantity of castings, and an upraised tuyere, the quantity of steel is more considerable. This primitive process is favourably spoken of by M. Brongniart. The weight of the lump of metal varies from 200 to 400 pounds. As the consumption of charcoal is very great, amounting in the Palatinate or Rheinhessen to seven times the weight of iron obtained, though in the Pyrenees it is only thrice, the Catalan forge can be profitably employed only where wood is exceedingly cheap and abundant.

The *Furnace à piece* of the French, or *Stuck-ofen* of the Germans, resembles fig. 573 (Copper), the tuyere (not shown there) having a dip towards the bottom of the hearth, where the melted matter collects. When the operation is finished, that is at least once in every 24 hours, one of the sides of the hearth must be demolished, to take out the pasty mass of iron, more or less pure. This furnace holds a middle place in the treatment of iron, between the Catalan forge and the cast iron *Fluss-ofen*, or high-blast furnaces. The *stuck-ofen* are from 10 to 15 feet high, and about 3 feet in diameter at the hearth. Most commonly there is only one aperture for the tuyere and for working; with a small one for the escape of the slag; on which account, the bellows are removed to make way for the lifting out of the lump of metal, which is done through an opening left on a level with the sole, temporarily closed with bricks and potter's clay, while the furnace is in action.

This outlet being closed, and the furnace filled with charcoal, fire is kindled at the bottom. Whenever the whole is in combustion, the roasted ore is introduced at the top in alternate charges with charcoal, till the proper quantity has been introduced. The ore falls down; and whenever it comes opposite to the tuyere the slag begins to flow, and the iron drops down and collects at the bottom of the hearth into the *manne* or *stuck*; and in proportion as this mass increases, the *flasse hole* for the slag and the tuyere is raised higher. When the quantity of iron accumulated in the hearth is judged to be sufficient, the bellows are stopped, the scoria are raked off, the little brick wall is taken down, and the mass of iron is removed by rakes and tines. This mass is then flattened under the hammer into a cake from 3 to 4 inches thick, and is put into two

lumps which are submitted to a new operation, where it is treated in a peculiar refinery, lined with charcoal *braguer*, and exposed to a nearly horizontal blast. The above mass seized in the jaws of powerful tongs, is heated before the tuyere; a portion of the metal flows down to the bottom of the hearth, loses its carbon in a mass of rich slags or fused oxides, and forms thereby a mass of iron thoroughly refined. The portion that remains in the tongs forms *bessemer*, which is drawn out into bars.

This process is employed in Cornwall for making a granular grade of iron. The mass of steel amounts to from 15 to 20 hundred-weight at the close of a run of 24 hours. Eight strong men are required to lift it out, a dolly carry it under a large hammer, where it is cut into pieces of about 1 cwt. each. These are afterwards rolled, and drawn into bars as above described. These furnaces are now almost generally abandoned in the Continent, in favour of *charcoal high or blast furnaces*.

Fig. 1042 represents a *scharstufen* (but without the tuyere, which may be supposed to be in the usual place), and is, like all the continental *Häute Föurneaus*, remarkable for the excessive thickness of its masonry. The charge is put in at the throat, near the summit of the octagonal or square cone, *ways*, for they are made of both forms. At the bottom of the hearth there is a dam-stone with its plate, for permitting the overflow of the slag, while it makes the surface of fluid metal, as well as a type stone with its plate, which forms the key to the front of the hearth; the *bushes* are a wide funnel, almost flat, to contract the easy descent of the charges, whereby the smelting with charcoal would proceed too rapidly. The bottom of the hearth is constructed of two large stones, and the hinder part of one great stone, called in German *backstein* (back stone), which the French have corrupted into *rustine*. In other countries of the Continent, the bushes are frequently a good deal more tapered downwards, and the hearth is larger than here represented. The refractory nature of the Häute iron ores is the reason assigned for this peculiarity.

In Sweden there are blast-furnaces, *scharstufen*, 35 feet in height, measured from the bushes above the line of the hearth, or *crucet*. Their cavity has the form of an elongated ellipse, whose small diameter is 6 feet across, at a height of 14 feet above the bottom of the hearth; hence, at this part, the interior space constitutes a belly corresponding with the upper part of the bushes. In other respects the details of the construction of the Swedish furnaces resemble the one figured above. Marcher has found that a furnace of that kind when height was only 30 feet, in which brown hematite of iron (*hematite*) was smelted, yielded 47 per cent in cast iron, at the rate of 5 hundred weight a day, or 36 hundred-weight one week after another; and that in the production of 100 pounds of cast iron, 170 pounds of charcoal were consumed. That furnace was worked with large bellows, mounted with leather.

The decarburization of cast iron is merely a restoration of the carbon to the surface in tracing inversely the same progressive steps as had carried it into the interior during the smelting of the ore. The oxygen of the air, acting first at the surface of the cast metal upon the carbon which it finds there, burns it; fresh charcoal, coming from the interior, comes then to occupy the place of what had been dissipated; this, finally, the whole carbon is transferred from the centre to the surface, and is there converted into either carbonic acid gas or oxide of carbon; for so direct experiment has hitherto proved which of these is the precise product of this combustion.

The diffusibility of carbon through the whole mass of iron constitutes a movement by means of which cast iron may be refined even without undergoing fusion, as is proved by a multitude of phenomena. Every workman has observed that steel loses a portion of its ductile properties every time it is heated in contact with air.

On the above principle, cast iron may be refined at once operation. Three kinds of iron are susceptible of this continuous process:—1. The speckled cast-iron, which contains such a proportion of oxygen and carbon as with the oxygen of the air and the carbon of the fuel may produce sufficient and complete saturation, but nothing in excess. 2. The dark grey cast iron. 3. The white cast-iron. The nature of the crude metal requires variations both in the form of the furnaces, and in the manipulations.

Indeed malleable iron may be obtained directly from the ores by one fusion. This mode of working is practised in the Pyrenees to a considerable extent. All the ores of iron are not adapted for this operation. Those in which the metallic oxide is mixed with much earthy matter, do not answer well; but those composed of the pure

black oxide, red oxide, and carburets, cannot break loose. To extract the metal from this mass, it is sufficient to expose (them to a high temperature, in contact first with charcoal, and with subsequent gases; the sulphur and iron are separated, but which covers the iron, forms a thin and compact crust, which the charcoal and water destroy, so that it is fit to receive the metal. When such a layer is as thick as a finger, it is put into the low furnace called *Coulée*, the ore with the charcoal pass with great rapidity, and in which the metal with the first is easily separated, they would be found in the crucible of *haut four*, a red-hot mass, round of a lump of metal.

In roasting and reducing by a furnace, several different operations may be distinguished. 1. The roasting of the ore to expel the sulphur, which would be lost easily if roasted afterwards. The roasting is done in a kiln, also the water, the carbon, and any other volatile substance, which the metal may contain. 2. The reduction and reduction to a mass by exposure to charcoal or to a hot gas. 3. The roasting, separation, and reduction of the metal, for the heavy metals where it is a nerve. There are several types in which these three operations will be combined, and in a single step, because, although the operations are performed at different stages, the process is continuous. In other types, the operations are performed at different stages, but in each stage of the work, three operations of the kind are known to exist: 1. The *Coulée* method, 2. The *Coulée* with wood charcoal, and 3. The *Coulée* with water.

The furnace of *Coulée* are a kind of circular furnace, 14 in. in diameter, and 6 in. high. They are excavated in an area, or a small elevation of country, 5 or 10 feet long by 4 or 6 broad, and covered in with a chimney. This area is quite similar to that of the ordinary hearth of our blast furnace.

The tuyère stands 5 or 6 inches above the basin, and has a slight inclination downwards. In *Coulée*, and the whole portion of Italy, the *Malenco* process, the iron ore is an oxide, similar to the specular ore of the Lake. This ore contains a little water, some carbonic acid, and a little pyrites, but in small quantity. Before deoxidizing the ore, it is requisite to expel the water and carbonic acid combined with the oxide, as well as the sulphur of the pyrites.

The operations of roasting, reduction, fusion, and agglutination are executed in the same furnace. These are indeed divided into two stages, but the one is a continuation of the other. In the first, the two primary operations are performed at once—the reduction of a portion of the roasted ore is begun at the same time that a portion of the raw ore is roasted; these two substances are afterwards separated. In the second stage, the deoxidation of the metal is continued, which had begun in the first stage; it is then melted and agglutinated, so as to form a ball to be submitted to the *haut four*.

The roasted pieces are broken down to the size of nuts, to make the reduction of the metal easier. In executing the first step, the basin and area of the furnace must be lined with a *brasque* of charcoal dust, 3, 4, or even 5 inches thick over the *brasque* a mound is raised with lumps of charcoal, very hard, and 4 or 5 inches high. A semicircle is framed round the tuyère, the inner radius of which is 5 or 6 inches. This mass of charcoal is next surrounded with another pile of the roasted and broken ore, which must be covered with charcoal dust. The whole is sustained with large blocks of the raw ore, which form externally a third wall.

These three piles of charcoal, with roasted and unroasted ore, are raised in three successive beds, each 7 inches thick; they are separated from each other by a layer of charcoal dust of about an inch, which makes the whole 24 inches high. This is afterwards covered over with a thick coat of pounded charcoal.

The blocks of raw ore which compose the outward wall form a slope, the larger and stronger pieces are at the bottom, and the smaller in the upper part. The large blocks are sunk very firmly into the charcoal dust, to enable them better to resist the pressure from within.

On the bottom of the semicircular well formed within the charcoal lumps, kindled pieces are thrown, and over these, pieces of black charcoal; after which the blast of a water-blowing machine (*trappe*) is given. The fire is kept up by constantly throwing charcoal into the central well. At the beginning of the operation it is thrust down with wooden rods, lest it should affect the building, but when the heat becomes too intense for the workmen to come so near the hearth, a long iron rake is employed for the purpose. At the end of about 3 hours, the two processes of roasting and reduction are completely finished: then the raw ore no longer exhales any fumes, and the roasted ore, being softened, unites into lumps more or less coherent.

The workman now removes the blocks of roasted ore which form the outer casing, rolls them to the spot where they are to be broken into small pieces, and pulls down the *brasque* (small charcoal) which surrounds the mass of roasted ore.

The second operation is executed by cleaning the basin, removing the slag covering the basin above with 2 or 3 *brasques* (coats of pounded charcoal), and pulling up to

the right and the left two heaps of charcoal dust. Into the interval between these two heaps two or three baskets of charcoal are cast, and on the top some cakes of the reduced cruds are laid, and the blast is renewed. The cakes, as they heat, undergo a sort of ignition, or swelling, by the action of the partly gaseous and the unreduced black oxide present. Very fusible slags flow down through the mass, and the iron, reduced and melted, passes freely through the cones, and falls into the basin below. To the first parcel of cakes others are added in succession. In proportion as the slags proceed from the cones run down, and the melted iron falls to the bottom, the thin slag is run off by an upper overflow or *cho hol*, and the reduced iron kept by the heat of the partly oxidation, remains in the basin: all its parts are agglutinated, forming a soft mass, which is removed by means of a hooked pole in order to be forged. Each lump or bloom of malleable iron requires 2 hours and a half for its production.

The iron obtained by this process is in general soft, very malleable, and but little steely. In Cornica four workmen are employed at one forge. The product of their labour is only about 4 cwt. of iron from 10 cwt. of ore and 20 of charcoal, mixed with wood of beech and chestnut. Though there are remains on an average 65 per cent. of iron, only about 40 parts are extracted, evincing a prodigious waste, which remains in the slag.

The difference between the Cornish and the Catalonian methods consists in the latter roasting the ore at a distinct operation, and employing a second one in the reduction, agglutination, and refining of the metal. In the Catalonian forges, 100 pounds of iron are obtained from 300 pounds of ore and 310 pounds of charcoal, being a produce of only 33 per cent. It may be concluded that there is a notable loss, since the sparry iron ores, which are those principally used, contain on an average from 54 to 56 per cent. of iron. The same ores smelted in the ordinary blast furnace produce about 45 per cent. of cast iron.

On the Continent, iron is frequently refined from the cast metal of the blast furnaces by three operations, in three different ways. In one, the pig being melted, with a portion of water, a cake is obtained, which is again melted in order to form a second cake. This being treated in the refinery fire, is then worked into a bloom. In another system, the pig iron is melted and cast into plates: these are melted anew in order to obtain crude balls, which are finally worked into blooms. In a third mode of manufacture, the pig iron is melted and cast into plates, which are roasted, and then strongly heated, to form a bloom.

The French fusible ores, such as the silicates of iron, are very apt to smelt into white cast iron. An excess of fluxes, light charcoals, too strong a blast, produce the same results. A surcharge of ores which deranges the furnace and affords more slag mixed with much iron, too rapid a slope in the hearth, too low a degree of heat, and too great condensation of the materials in the upper part of the furnace, all tend also to produce a white cast iron. In its state of perfection, white cast iron has a silver colour, and a bright metallic lustre. It is employed frequently in Germany for the manufacture of steel, and is then called *steel steel*, or *lamellar steel*, a title which it still retains, though it be hardly silver white, and has ceased to be foliated. When its colour takes a bluish grey tinge, and its fracture appears striated or splintery, or when it exhibits grey spots, it is then styled *flower steel*. In a third species of white cast iron we observe still much lustre, but its colour verges upon grey, and its texture is variable. Its fracture has been sometimes compared to that of a broken cheese. This variety occurs very frequently. It is a white cast iron, made by a surcharge of ore in the furnace. If the white colour becomes less clear and turns black, if its fracture be contorted, and contains a great many empty spaces or air-cells, the metal takes the name of *carcrans steel*, or *timber steel*. The whitest metal cannot be employed for casting. When the white is mixed with the grey cast iron, it becomes *riband* or *trout cast iron*.

The German refining forge.—Figs. 1043, 1044, represent one of the numerous refinery furnaces so common in the Harz. The example is taken from the *Mansfeld* works, in the neighbourhood of Ellingerode. Fig. 1044 is an elevation of this forge. It is the refinery hearth, provided with two pairs of bellows. Fig. 1043 is a vertical section, showing particularly the construction of the crucible or hearth in the refinery forge. It is an overshot water wheel, which gives an alternate impulsion to the two bellows *b* by means of the revolving shaft *c*, and the cams or tappets *d* & *e* *g*.

The hearth is lined with cast-iron plates. Through the pipe *l*, cold water may be introduced, under the bottom plate *m*, in order to keep down, when necessary, the temperature of the crucible, and facilitate the solidification of the *knops* or bloom. An orifice *n*, figs. 1043, 1044, called the *cho* (flow hole), shows the melted slag or cinder to flow off from the surface of the melted metal. A copper pipe or nose piece conducts the blast of both bellows into the hearth, as shown at *b* & *c*, fig. 1044.

The train was followed to the south of railway by a grey car - a common coal car, from the works of Reichardt. The train is, being used and heaped over with iron

Next, open the side opposite to the tuy re *s.* *f.* 11, 12, 13, 14, long pipe of iron or
steel with a tapering spigot downwards, and be drawn upwards successively
to the hearth by a bell-poker, so that the extremity which may be placed in
the middle of the fire, at a distance of 6 or 8 inches from the mouth of the tuy re.
The working process in this way will be hastened, if a mass of metal to be raised
from the furnace, e. g. *fa* and *re* in drops to the bottom of the hearth, being
carried by the fluid and more vitreous matters more or less heated with it.
After raising them off by the crane, be then works the last iron by powerful air
blast with the *sa* bell (iron rod), till it is converted into mass of a past.

If, in this case, a portion of the carbon is oxidized to the east, the carbon is converted into a gas, and is carried in the form of carbon monoxide and carbon dioxide. When the lump is completely oxidized, the whole lump is covered with earth, and the heat so intense that it is fresh, and will explode all round it. The heat is so great that the remainder of the carbon, that is, the iron has been oxidized, is reduced. If the furnace is properly managed, the effect, two are given. If the furnace is not properly managed, it is a great deal of waste, but at a higher level, so that it remains in the state.

The weight of each *pu* or bloom is about 2 cwts., being the product of 4 cwt. and $\frac{1}{2}$ of pig iron; the loss of weight is therefore about 26 per cent. 149 pounds of charcoal are consumed for every 100 pounds of bar iron obtained. The whole operation lasts about 2 hours. The bellows are stopped as soon as the bloom is ready; this is immediately transferred to a force hammer, the cast iron head of which weighs 8 or 9 cwts. The bloom is greatly condensed thereby, and discharges a considerable quantity of semi-fluid cinder. The lump is then divided by the hammer and rolled into 4 or 6 pieces, which are re-heated, one after another, in the refinery fire, in order to be forged into bars, whilst another pig of cast iron is laid on its place, to prepare for the formation of a new bloom. The above process is called by the Germans *Aluap-fischen*, or lump refining. It differs from the *durch brech-fischen*, because in the latter the lump is not turned over in mass, but is broken, and exposed in separate pieces, solely to the refining power of the blast near the tuyes. The French call this *affinage par morceaux*, it is a simpler work than the

The quality of the iron is tried in various ways; as, first, by raising a bar by the anvil, with the two hands over one's head, and bringing it forcibly down to strike across a narrow anvil at its centre of percussion, or, one-third from the other extremity of the bar; after which it may be bent backwards and forwards at the place of percussion several times; 2, a heavy bar may be laid obliquely over the anvil's end, and struck strongly with a hammer with a narrow pane, so as to curve it in two opposite directions; or while heated to redness, they may be kneaded backwards and forwards at the anvil's point, to the edge of the anvil. This is a severe trial, which the best Swedish iron, bears surprisingly, emitting as it is hammered a pleasant odour, peculiar to it, and to the bar iron of Ulverstone, which also resembles it in furnishing a good steel. The forging of a horse-shoe is reckoned a good criterion of the quality of iron. Its freedom from flaws is detected by the above modes; and its linear strength may be determined by suspending a scale to the lower end of a hand-drawn wire, of a given size, and adding weights till the wire breaks. The tests of Marlow, Trodgold, Houghton, and Vair, may be resorted to with advantage.

on the mode of proving the strength of different kinds of iron, in a great variety of circumstances.

Dry assay of iron ore.—The object of a dry assay of an iron ore is to ascertain by an experiment on a small scale the amount of iron which the ore should yield when smelted on the large scale in the blast furnace. For this purpose the metal must be dissolved, and a heat of fusion produced as to melt the metal and the earths associated with it in the former, and the latter may be smelted as a slag, but at the bottom of the furnace, and the latter in a lighter slag or slag above it. Such a temperature may only be obtained in a small furnace connected with a chimney at least 12 feet in height, and which may expressly for smelting the furnace, is generally built of such a size that four assays may be made at the same time, viz. about 14 inches square, and 12 feet in depth from the outer side of the cover to the movable bars of iron which form the grate. In order that the substance smelted with the iron in the ore should form a fusible compound, it is usually required to add a flux, the nature of which will depend upon the character of the ore and the exact nature of the impurities. Berthier divides iron ores into five classes: 1. *Iron almost pure, such as the magnetic oxide, oligistic iron, and the hematite*; 2. *Ores containing silica, but free or nearly so from any other substance*; 3. *Ores containing silica and various bases, but little or no lime*; 4. *Ores containing one or more bases, and no lime*; 5. *Ores containing silica, oxide of titanium, oxide of chromium, or oxide of tungsten, but little or no lime*; 6. *Ores containing silica, lime, and a little iron, and which are fusible alone*. Ores of the first class may be reduced without any flux, but it is always better to employ one, as it greatly facilitates the formation of the button; borax may be used, or, better, a fusible earthy silicate, such as ordinary flint glass. Ores of the second class require some base to serve as a flux, such as carbonate of soda, a mixture of carbonate of lime and clay, or of carbonate of lime and dolomite; ores of the third class are mixed with carbonate of lime in the proportion of from one-half to three-fourths of the weight of the foreign matter present in the ore. Ores of the fourth class require as a flux silica in the form of powdered quartz, and generally also some lime; the magnesian spathic ores which belong to this class may be smelted with the addition of silica alone, but the magnesian spathic ores require lime. Ores of the fifth class require no flux.

Method of conducting the assay.—One hundred grains of the ore finely pulverised and passed through a silk sieve are well mixed with the flux, and the mixture introduced into the small concavity made in the centre of a crucible that has been lined with charcoal; the lining of the crucible is effected by partially filling it with coarsely powdered and slightly damped charcoal or *braque*, which is then rammed into a solid form by the use of a light wooden pestle. The mingled ore and flux must be covered with charcoal. The crucible thus filled is closed with an earthen lid (lined with fire clay) and it is then set on its base in the air furnace. The heat should be very slowly raised, the damper remaining closed during the first half-hour. In this way the water of the damp charcoal exhales slowly, and the distillation of the ore is completed before the fusion begins; if the heat were too high at first the luting would probably split, and moreover, the slag formed would disintegrate on cooling of iron, which would be lost to the button, and thus give an erroneous result. After half an hour the damper is gradually opened, and the furnace being filled with fresh coke, the temperature is raised progressively to a white heat, at which point it must be maintained for a quarter of an hour; the damper is then closed and the furnace allowed to cool. As soon as the temperature is sufficiently reduced, the crucible is removed and opened over a sheet of brown paper; the *braque* is carefully removed, and the button of cast iron taken out and weighed. If the experiment has been entirely successful the iron will be found at the bottom of the crucible in a small rounded button, and the slag will be entirely free from any adhering metallic matter, and will resemble in appearance green bottle glass; should, however, the crucible contain small metallic particles, the experiment is not necessarily a failure, as they may generally be recovered by washing and the magnet. But if on breaking the crucible, the reduced metal should be found in a partially melted state and not collected into a distinct mass, it indicates either too low a temperature or an improper selection of fluxes, and the experiment must be repeated. The iron obtained is not chemically pure, but contains carbon, and if the ore is manganesiferous, manganese; the result is therefore somewhat too high, though indicating with sufficient exactness for all manufacturing purposes the richness of the ore assayed.

Humid assay of iron ore.—The quantitative determination of the various substances that occur in iron ores, demands on the part of the operator a considerable amount of skill and patience, and can only be profitably undertaken by those who have acquired in the laboratory a thorough acquaintance with analytical operations. As, however, much attention has of late years been bestowed on the composition of

Dissolution of the remaining iron salts — 25 or 30 grains of the finely powdered ore are dissolved for at least an hour with strong hydrochloric acid, diluted with boiling distilled water and filtered. The residue on the filter being thoroughly washed, the solution is peroxidised, if necessary, by the addition of chlorate of potash, and is neutralised by ammonia, boiled with excess of acetate of ammonia, and rapidly filtered while hot; the filtrate (which would be colourless) together with the washings, is removed in a flask, ammonia is added, and then a few drops of bromine, and the flask closed with a cork. In a few minutes, if manganese be present, the liquid acquires a dark colour; it is allowed to remain at rest for 24 hours, then warmed, and rapidly filtered and washed; the brown substance on the filter is hydrated oxide of manganese, it loses its water by ignition, and then becomes MnO_2 , 100 parts of which correspond to 67 parts of protoxide.

The liquid filtered from the manganese contains the lime and magnesia; the former is precipitated by oxalate of ammonia, and the oxalate of lime formed converted by ammonium carbonate, in which state it is either washed, having been previously evaporated with carbonate of ammonia, or it is converted into carbonate by the addition of a few drops of sulphuric acid, evaporation, and ignition. The lime being separated, the magnesia is thrown down as ammonio magnesia phosphate by phosphate of soda and ammonia, and after standing for 24 hours it is collected on a filter, washed with cold ammonia water, dried, ignited, and weighed; 100 parts of carbonate of lime correspond to 60 of lime; 100 parts of sulphate of lime to 40.1 of lime, and 100 parts of pyrophosphate of magnesia to 35.7 of magnesia.

The red precipitate collected on the filter after the boiling with acetate of ammonia, consists of the basic acetates of iron and alumina, together with the phosphoric acid. It is dissolved in a small quantity of hydrochloric acid, and then boiled in a silver or platinum basin with considerable excess of pure caustic potash; the alumina (with the phosphoric acid) is hereby dissolved, the insoluble portion is allowed to subside, and the clear liquid is then decanted, after which the residue is thrown on a filter and washed; the filtrate and washings are supersaturated with hydrochloric acid, nearly neutralised with ammonia, and the alumina finally precipitated by carbonate of ammonia. From the weight of the ignited precipitate, the corresponding amount of phosphoric acid determined by a separate operation is to be deducted, the remainder is calculated as alumina. The residue left after digesting the ore with hydrochloric acid, consists principally of silica, but it may also contain alumina, peroxide of iron, lime, manganese, and potash. For practical purposes it is rarely necessary to submit it to minute examination; should such be desired, it must be dried, ignited, and weighed, then fused in a platinum crucible with four times its weight of fused alkaline carbonates, the fused mass dissolved in dilute hydrochloric acid, and evaporated to dryness, the residue washed with strong hydrochloric acid, and after standing at rest for some hours, redissolved in hot water, filtered, and the acids on the filter washed and weighed. The alumina, lime, oxide of iron, and manganese in the filtrate are separated from each other according to the instructions given above; the potash is estimated by a standard process.

Carbon and loss — The coal, which constitutes a considerable part of the weight of that large and important class of ores the *clay iron-stones*, is estimated by noting the loss sustained after adding to a weighed portion of the ore sulphuric acid, and thus evolving the gas; or more roughly, by the loss sustained in the entire analysis. Another method is to fuse 20 or 25 grains of the ore with 60 or 80 grains of dry borax, and noting the loss, which consists of water and carbonic acid; by deducting the water obtained in a previous experiment, the quantity of carbonic acid is obtained. This method, however, can scarcely be recommended, on account of the contraction of the crucible, though the results are very accurate.

Determination of the iron — This is performed on a separate portion of the ore, either by the volumetric method of Marguerite, or by that of Dr. Penny; both give very exact results. Marguerite's method is based on the reciprocal action of the salts of protoxide of iron and permanganate of potash, whereby a quantity of the latter is decomposed exactly proportionate to the quantity of iron. The ore (about 10 or 15 grains) is dissolved in hydrochloric acid, and the metal brought to the minimum of oxidation by treating the solution with sulphate of soda (or better, sulphate of ammonia), and boiling to expel the excess of sulphurous acid; the solution of permanganate of potash is then cautiously added drop by drop, until the pink colour appears, and the number of divisions of the burette required for the purpose accurately noted. The solution should be considerably diluted, and there must be a sufficient quantity of free acid present to keep in solution the peroxide of iron formed and also the oxide of manganese. The whole of the iron must be at the minimum of oxidation, and the excess of sulphurous acid must be completely expelled; if the latter precaution be neglected an erroneous result will be obtained, as the sul-

plaster will well take oxygen from the peroxide of iron, and thus react in the same manner as iron.

To prepare the peroxide of protoxi, 7 parts of carbonate of potash, 10 parts of hyposulphite of potash, and 5 parts of peroxide of manganese are commonly used. The carbonate must be in the finest possible powder, and the potash having been dissolved in water, is mixed with the other substances, and the whole formed in very small masses for use here. The fluid mass is dissolved with water, so as to obtain as concentrated a solution as possible, and about twice as much added for the usual quantity of a cubic foot of water, to be afterwards filtered through asbestos. The solution must be freed from the matters of organic matter, and kept in a glass stoppered bottle. If the solution be evaporated it yields beautiful red osmose crystals; it is better in supplying the crystals in the preparation of the test liquor, as the solution keeps much better when no carbonate is present. To prepare the osmose of iron liquor, a certain quantity, say 1 lb. weight, of pure iron wire is dissolved in part by osmose acid, after the decomposition of the liquor has ceased, and the solution is complete, the liquor is diluted with about a pint of water, and immediately divided by evaporation into two equal parts, the smaller to support solution of the residue of peroxide of iron, and the greater to produce the pink colour is immediately used; and this number is then multiplied by 10000, giving the result of the analysis of iron. A small amount of iron is more by dissolving long grains of the crystallized peroxide in 1 cubic grain of water.

Penny's method is based on the reciprocal action of chlorine and suboxide of iron, whereby a fraction of oxygen takes place, the peroxide of iron forming osmose, and the peroxide of iron and the residue acid thus equivalent of chlorine. The process is performed as follows:—A convenient quantity of the osmose is reduced to coarse powder, and one half at least of this is still further pulverized, and it is no longer only between the fingers. The best solution of bichromate of potash is next prepared: 444 grains of the salt in one pint of water are weighed out, and put into a beared graduated bottle 100 equal parts, and when dissolved water is afterwards poured in until the structure is filled to 0. The plug of the bottle is then loosely placed on the top, and the contents are stirred by repeatedly turning the bottle up and down, and the solution colored red if necessary by the addition of 2. Each division of the solution thus prepared contains 444 grains of bichromate, which Dr. Penny ascertained to correspond to half a grain of metallic iron. The bichromate must be pure, and should be thoroughly dried by being heated in a glass bottle. 10 grains of the pulverized osmose are now introduced into a Florence flask with 1½ oz. by measure of strong hydrochloric acid and 1 pint of distilled water. Heat is occasionally applied, and the mixture continuously agitated until the osmose is dissolved by the escape of carbonic acid gases, the heat is then removed, and the mixture made to boil and kept at moderate ebullition for an hour, or a quarter of an hour. About 6 oz. of water are next added and mixed with the contents of the flask, and the whole filtered into an evaporating basin. The flask is rinsed several times with water, to remove all adhering solution, and the residue on the filter is well washed. Several small portions of a weak solution of red prussiate of potash (containing 1 part of salt to 40 water) are now dropped upon a white porcelain slab, which is conveniently placed for testing, the solution in the basin during the heat operation. The prepared solution of bichromate of potash in the burette is then added very cautiously to the solution of iron, which must be repeatedly stirred, and as soon as it assumes a dark greenish shade it should be occasionally tested with the red prussiate of potash. This may be easily done by taking out a small quantity on the end of a glass rod, and mixing it with a drop of the solution in the porcelain slab. When it is found that the last drop runs out a distinct blue tinge, the operation is terminated, the burette is allowed to drain for a few minutes, and the number of divisions of the test liquor consumed read off. This number multiplied by 2 gives the amount of iron per cent. The necessary calculation for ascertaining the corresponding quantity of protoxide is obvious. If the specimen should contain iron in the form of peroxide, the hydrochloric solution is decolorised as before by sublimation of ammonia. The presence of peroxide of iron in an ore is easily detected by dissolving 50 or 60 grains in hydrochloric acid, diluting with water, and testing a portion of the solution with red prussiate of potash. If a decided blood-red colour is produced, peroxide of iron is present. If it be desired to ascertain the relative proportions of peroxide and protoxide of iron in an ore, two operations must be performed:—one on a quantity of the ore that has been dissolved in hydrochloric acid in a stout stoppered bottle; and another on a second quantity that has been dissolved as usual, and then decolorised by sulphite of ammonia or by metallic zinc. It is advisable to replace the solution of bichromate much weaker than proposed by Dr. Penny, and to employ a burette graduated to cubic millimetres. A good strength is 1 grain of metallic iron in 10 cubic centimetres of solution.

Metals precipitable by sulphuric acid.—The hydrochloric acid is washed portion of the ore very finely, and is then dissolved for a considerable time in hydrochloric acid; the solution is filtered; the iron in the filtrate is precipitated by necessary by sulphate of ammonia, and a current of sulphuretted hydrogen passed through it. A small quantity of sulphuric acid is always added to the filtrate on a filter, and thoroughly washed; it is then evaporated at us as a precipitate as possible. The residue (if any) is mixed with carbonate of soda, and blown off with a blast of air, or with the blowpipe; any portion of metal that may be obtained is removed and dried.

Analysis of pig-iron.—The most important constituents to be determined are iron (combined and uncombined), carbon, sulphur, phosphorus, traces of lead, manganese, or of more rare elements, are manganese, arsenic, copper, zinc, chromium, titanium, cobalt, nickel, tin, aluminium, selenium, molybdenum, and the salts of the alkalis.

1. *Determination of the total amount of carbon.*—About 1 grain of the iron is dissolved in 20 cc. of water and 2 cc. of concentrated hydrochloric acid. The solution is allowed to proceed until all, or nearly all, the iron is dissolved. Carbon and iron are left insoluble; they are filtered on a filter, washed with dilute hydrochloric acid (to prevent the precipitation of soluble copper, iron, and with water, then with dilute caustic soda, and finally with boiling water. The washed carbon and copper are dried on the filter, from which they are removed by a hot plate, and are mixed with oxide of copper, and burned in a glass tube in the usual way, with a current of air, or, still better, of oxygen. The carbonic acid is collected in Liebig's apparatus, from which the amount of carbon is calculated.

2. *Graphite, or uncombined carbon.*—A weighed portion of the finely divided iron (flasks or borings may be used) is digested with moderately strong hydrochloric acid, the combined carbon is evolved in combination with hydrogen, while the graphite is left undissolved. It is collected on a filter, washed, and then boiled with a solution of caustic potash, sp. gr. 1.37, in a silver dish; the solution which contains the iron in the form of silico-iron is thereby dissolved; the clear caustic solution is drawn off by a pipe or syphon, and the black residue repeatedly washed; it is dried at as high a temperature as it will bear, and weighed; it is then heated in a current of air, until the white of the carbon is burnt off. A residue remains, which is weighed, and the weight deducted from that of the original black residue, the difference gives the amount of graphite.

3. *Silicon.*—The amount of this element is determined by evaporating to dryness a hydrochloric solution of a weighed quantity of the metal. The dry residue is digested with hydrochloric acid, filtered with water, boiled and filtered; the residue on the filter is washed, dried, and ignited, and the whole of the residue is weighed; it is then washed after which, it is digested with solution of potash, and the residue, if any, washed, dried, ignited, and weighed; the difference between the two weights gives the amount of silicon. 100 parts of which metal = 47 parts of silicon.

4. *Phosphorus.*—A weighed portion of the metal is dissolved in nitric acid, evaporated to dryness, and the residue redissolved with hydrochloric acid. The solution is treated precisely as recommended for the determination of phosphoric acid in ores; every 100 parts of pyrophosphate of magnesia indicate 25.36 parts of phosphorus.

5. *Sulphur.*—In pig-iron this element is very conveniently and accurately estimated by allowing the gas evolved by the action of hydrochloric acid on a weighed quantity (about 100 grains) of the metal, to pass slowly through a solution of acetate of lead acidified by acetic acid. Sulphur, the whole of which takes the form of sulphuretted hydrogen, enters into combination with the lead, forming a black precipitate of sulphide of lead, which is collected, washed, and converted into sulphate of lead by digesting it with nitric acid, evaporating to dryness, and gently heating to 100 parts sulphate of lead = 10.55 sulphur. The most minute quantity of sulphur in iron is detected by this process. If, however, crude white iron is under examination, this method does not give satisfactory results, on account of the difficulty with which it is acted upon by hydrochloric acid; it is better, therefore, to treat the metal with nitro-hydrochloric acid, evaporate to dryness, re-digest with hydrochloric acid, and then precipitate the filtered solution with great excess of chloride of barium; or the finely divided metal may be fused in a gold crucible with an equal weight of pure nitrate of soda and twice its weight of pure alkaline carbonates; the fused mass is extracted with water acidified with hydrochloric acid, and finally precipitated by chloride of barium.

Manganese.—The metal is determined by the process described for its estimation in ores; the iron must exist in the solution in the form of sesquioxide.

Arsenic and copper.—The nitro-hydrochloric solution of the metal is evaporated to dryness, re-digested with hydrochloric acid, and filtered. The iron in the clear

residue is removed to prevent its being mixed with a sufficient quantity of sulphuric acid, the solution is heated till it has the appearance of castile soap. It is then separated with water, distilled water, and a new distillation is performed in a small vessel, the excess of gas is boiled off, and the precipitate, if any, removed on a small filter and well washed; it is then mixed with a small quantity of potassium which dissolves the sulphate of arsenic, leaving the sulphate of copper. The latter is decomposed by heating with nitric acid, and the presence of copper is proved by the addition of ammonia, which produces a blue color; the sulphate of arsenic is precipitated from the solution in the shape of potassium by dilute sulphuric acid; it may be redissolved in aqua regia, and the filtrate solid having been exposed by evaporation, the residue may be analyzed as Marsh's arsenic.

Antimony and tin.—These metals, if present, will be found in the residue from which the copper and arsenic have been precipitated by sulphuretted hydrogen. The solution is percolated, and the superoxide of iron precipitated by slight excess of carbonate of baryta, after which the solution is treated as just directed by sulphate of magnesia.

Chromium and manganum.—These metals which should be looked for in the carbonaceous residue obtained by dissolving a small quantity of the sample in dilute hydrochloric or sulphuric acid are dissolved in fuming nitric acid. The filtered solution is intimately mixed with an excess of weight of iron, and exposed for an hour in a current of a good gas jet. When cold the mass is powdered and treated with water. The filtered solution is gradually mixed and well stirred with nitric acid, taking care that it may not remain slightly alkaline, and that no chromic acid is liberated which would render the residue and chromic acids. The solution is then mixed with an excess of solution of chloride of barium as long as any precipitate is produced. The precipitate, which consists of vanadate and chromate of baryta, is dissolved with slight excess of dilute sulphuric acid, and filtered. The filtrate is evaporated with ammonia, concentrated by evaporation, and a fragment of chloride of ammonium placed in it. In proportion as the solution becomes impregnated with soluble of potassium, manganate of ammonia is deposited as a white or yellow crystalline powder. To test for chromium only, the solution is treated with water, extracted with water, and then boiled with carbonate of ammonia; the solution is neutralized with acetic acid, and then acetate of lead added; the production of a yellow precipitate indicates chromium.

Iron.—The metal is best separated from iron, by first reducing the latter to the state of protoxyde by sulphate of ammonia, then neutralizing with carbonate of soda, and afterwards boiling with excess of caustic potash, until the precipitate is black and pulverulent. The solution is then filtered off, and the acidulated with hydrochloric acid, and the alumina precipitated by sulphate of ammonia.

Calcium and magnesium.—These metals are found in the solution from which the iron and aluminium have been separated; they both exist probably (together with the aluminium) in the cast iron in the form of slag, and are best detected in the black residue which is left on dissolving the iron in dilute sulphuric or hydrochloric acid. After digesting this residue with caustic potash, and burning away the graphite, a small quantity of a red powder is left, which is composed of chromic acid, oxide of iron, alumina, lime, and magnesia; if 300 grains of cast iron are operated upon, a sufficient quantity of insoluble residue will be obtained for a quantitative determination of its constituents.—H. M. N.

IRON BRIDGE. See TRUSS.

ISINGLASS (*Galle de Poisson*, Fr.; *Husenblase*, Germ.), *Ichthyocolia*, *ἰχθυόcolla*, from *ἰχθῆρ*, a fish, and *κόλλα*, glue, or Fish glue, is a whitish, dry, tough, semi-transparent substance, twisted into different shapes, often in the form of a lyre, and consisting of membranes rolled together. Good isinglass is unchangeable in the air, has a leathery aspect, and a marked tone, nearly insipid when steeped in cold water it swells, softens, and separates in membranous laminæ. At the boiling heat it dissolves in water, and the solution, on cooling, forms a white jelly, which is semi-transparent, soluble in weak acids, but is precipitated from them by alkalis. It is gelatinous, nearly pure; and if not brittle, like other glue, this depends on its fibrous and elastic texture. The whitest and finest is preferred in commerce. Isinglass is prepared from the air-bladders of sturgeons, and especially the great sturgeon, the *Acipenser huso*, which is fished on the shores of the Caspian Sea, and in the rivers flowing into it, for the sake chiefly of its swimming bladder. It is also obtained from the *A. stellatus*, and the *A. Goldensteinii*. We are informed that in Russia the *Siberian glanis* is also caught for the purpose of obtaining isinglass.

The preparation of isinglass in Russia, and particularly at Astracan, consists in steeping the swimming bladders in water, removing carefully their external coat, and the blood which often covers them, putting them into a dampen-bag, squeezing them, softening them between the hands, and twisting them into small cylinders. They are

ready for the market is made only after being dried in the sun, and washed with the juice of burning sulphur.

In some districts of Malavia, another process is followed. The skin, the stomach, the intestines and the swimming bladder of the eel are cut in small pieces, steeped in cold water, and then gently boiled. The jelly thus obtained is spread in thin layers to dry, when it assumes the appearance of parchment. This being softened in a little water, then rolled into cylinders, or extended into plates, constitutes an inferior article.

The swimming bladder of the eel and many other fishes, also furnishes a species of isinglass, but it is much more membranous, and less soluble than that of the sturgeon.

The properties of isinglass are the same as those of gelatine or pure glue, and its uses are very numerous. It is employed in considerable quantities to clarify ale, wine, liquors, and coffee. As an article of food to the luxurious in the preparation of creams and jellies, it is in great request. Four parts of it convert 100 of water into a transparent jelly, which is employed to enrich many soups and sauces. It is used along with gum as a dressing to give lustre to ribbons and other silk articles.

It is by covering thin silk with a coat of isinglass that court water is made. A solution of isinglass covered with carmine forms an excellent injection liquor to the anatomist. M. Roehen has made another pretty application of isinglass. He plunges into a liquid solution of it, made by means of a water-bath, sheets of wire gauze set in window or lamp frames, which, when cold, have the appearance of glass, and answer instead of it for shades and other purposes. If one dip be not sufficient to make a proper transparent plate of isinglass, several may be given in succession, all within such film to harden in the interval between the dips. The outer surface should be varnished to protect it from damp air. These panes of gelatine are now generally used for lamps instead of glass, in the maritime arsenals of France. — See GELATINE.

Isinglass is known commercially as *Leaf isinglass*, *Long and short staple*, and *Black isinglass*. Dr. Royle speaks of the *Simorey leaf*, *bush*, and *long and short staple*. In his paper on the *Production of Temphoo along the coasts of India*, which a *Notice of its Fisheries*. We receive from the *Brasil, Pipe, Lump, and Home-cumb Isinglass*.

Our importations of isinglass in 1856 and 1857, were

ISOMERISM, from *isos*, equal, and *meros*, part. Identity of elements and proportions with variations in physical properties. Thus, oil of turpentine and oil of citron are isomeric, each having the composition $C_{10}H_{16}$. The study of the laws of atomic constitution is one of the most important within the range of physico-chemical science, and beyond all others, it demands the highest powers of the philosopher, united with the mechanical care of the microscopic analyst. The tendency of science leads to the conviction that many of the bodies which we now regard as distinct elements are only isomeric; and such groups as chlorine, iodine, bromine, and fluorine, as sulphur, selenium, and boron, and as carbon and silicon, may with the advance of our knowledge be shown to be modified conditions of one form of matter. This subject will be fully treated in *Frederick's Dictionary of Chemistry*.

ISOMORPHISM. M. Scherer was the first to observe that many groups of substances, simple or compound, having an analogous constitution, crystallise in forms of the same crystalline character, or differ but little in their angles. Thus, *alumina*, *red oxide of iron*, and *oxide of chrome* crystallise in forms of the rhombobedral system.

Carbonate of lime, *carbonate of magnesia*, *protosulphate of iron*, *protosulphate of manganese*, and *oxide of lime* are also isomorphous forms belonging to the rhombobedral system.

Structure of dentine, papilla of enamel, and mode of local extension in some species of the mammalian group.

The subject-matter of the law, was addressed and Master M. Manning and Doctor S. S. M. Manning.

IVORY. (*Forr. Fr. Elephant, Germ.*) The common name of the tusk is that of the elephant, and of the tusk of the hippopotamus, and the term of the tusk.

From a valuable paper read by Professor Owen before the Society of Arts in December, 1834, we extract the following important notices as to the growth and structure of ivory.

"The structure of the tusk of other animals, beside the elephant, is an article of common knowledge; but the same theory was given in the paper submitted of the tusk of all animals, but it is here, by the best anatomical and physiological reasoning, in the most concise of details, in such a manner, which is necessary to be understood, shows some lines of identical nature, as well as pointing to the use of it, and showing by their structure, as well as by their shape, that they are, in fact, the same kind of tusk, and from every consideration, whether derived from their form, or from their structure, the same general conclusion is arrived at, which is no other than that of a tusk of ivory. Although, however, in other animals except those to the elephant, the tusk is not of the same shape, and is not made in many other species of animals, which, from their structure, and the similarity of their principal structure, are not of the same shape, and are not of the same shape, true ivory is used; and some of these cases, such as those of the large tusk of the hippopotamus, are more valuable for certain purposes, especially in the manufacture of articles, than by the tusk, than any other kind of tusk. The utility of tusk in commerce, and in the art, depends chiefly on a peculiar nature that it has in their mode of growth. For the first part, as a tusk, it is, having attained a certain size and shape, used to grow. They are composed of a series of the same, in which they are built through daily use, and when worn away, or affected by decay, they perish. Teeth, in the kind, are not of the same growth, but they are of the same, such as the first teeth of the rat, rabbit, and all the teeth in the tusk of the lion and hippopotamus, the long ascending canine teeth of the walrus, the still longer spurs of the walrus, the tusk of the walrus, and the very tusk of the elephant, which are removed with the property of perpetual growth, that is, they grow as long as the animal lives.

"In tusk of animal growth, such as the tusk, and in some instances, and such enamel (or ivory) are formed, and added to the pre-existing substance of the tusk matrix, in proportion as those are calcified, or converted into tusk, and as fast as the ivory and enamel may be worn away from the summit of such a tusk, new ivory and enamel be formed at its base, and thus the growth of the tusk is not interrupted. The rate of the addition of the formative principle is at first greater than the rate of abrasion, and the tusk not only grows, but increases in size. When, however, the animal has attained its full growth, the tusk for the most part is reproduced without increase of size, or at most, increases only in length, and that in some cases, its summit is not perpetually worn down by being opposed to that of an opposite tusk."

With respect to the distribution of the elephant, the same high authority has the following remarks:—

"In the present creation, elephants are restricted to the African and Asiatic continent. The African elephant, as is well known, is a distinct species from the Asiatic one; and some of the Asiatic elephants of the larger size of the Indian Asiatic, as those of Sumatra, if not actually distinct from the elephants of Ceylon and Java, form, at all events, a strongly marked variety. With reference, however, to the commercial relations of ivory, it is chiefly worthy of notice that in the Asiatic elephants, tusks of a size which gives them the value of ivory in commerce, are peculiar to the male, whilst in the African elephants, both males and females afford good sized tusks, although there is a sexual difference of size in this species, those of the male being the largest. In former times, and, as it would seem, before man existed to avail himself of this beautiful animal substance for use or ornament, the large animals having true ivory-probably quadrupeds, as they are termed, from their peculiar prehensile nasal appendage, were much more widely spread over the globe, and existed in far greater numbers than in the present day, more numerous in individuals, more numerous in species, exhibiting so great diversity in the conformation of their grinding teeth, as to have led the naturalist and the philosopher to divide them into two genera, called *Elephas* and *Mastodon*. A true elephant trampled in countless herds over the temperate and northern parts of Europe, Asia, and America. This was the creature called by the Russians, Mammoth; it was mainly clad with

hairs and fur, is derived from an animal deriving sustenance from the leaves and branches of trees, which grow as low as the black berries of north latitude. Some of the ivory of commerce is, instead of being derived from the tusk of this animal, taken from the jawbone of the walrus.

The ivory of the tusk of the African elephant is most esteemed by the manufacturer for its density and whiteness.

The outside of the tusk of the elephant is covered by the cortical part, which is softer and less compact than the interior substance, with the exception of the two sides that meet there, being the hardest cavity. The hardest, toughest, whitest, and most translucent ivory has the preference in the market; for many purposes the horn of the narwhal being considered the best. The horn of the narwhal is sometimes used for the same purposes as ivory.

The ivory of the humpback whale is preferred by dentists; it is much harder than that of the elephant, its surface is a pearly white, and it is almost free from grain. The teeth of the walrus, sometimes called the walrus jaw, which being perforated from the upper jaw, are also used for the same purposes. The most common kind of ivory of the humpback whale are occasionally used as ivory; those of the sperm whale are of a pearly oval section, and resemble ivory in appearance, but they are dark coloured towards the centre, and surrounded by an oval band of white ivory.

Ivory has been used for ornamental works from the earliest periods. It has been used to have been found for his works only in ivory combined with gold, and attributed to the Egyptians. The ivory statues of the ancients appear to have been carved from a single piece of ivory, and covered with gold or ivory.

In our days ivory has been extensively employed by the miniature painter; it is used by the carver in the manufacture of numerous useful and ornamental articles; the carver makes the bone handle from it, and the philosophical instrument maker constructs his scales from this material.

When ivory shows cracks or fissures, it is a substance, and when a splinter broken off by a dull aspect, it is reckoned of inferior value. Ivory is distinguished from bone by a peculiar semi-transparent rhomboidal net-work, which may be readily seen in a piece of ivory cut transversely.

Ivory is very apt to take a yellow brown tint by exposure to air. It may be whitened or bleached, by rubbing it first with pounded pumice-stone and water, then placing it under a glass shade luted to the side at the bottom, and exposing it to sunlight. The same result without the shade would be apt to destroy the surface of the ivory. The most rubbing and exposure may be repeated several times.

For etching ivory a ground mass by the following recipe is to be applied to the polished surface.—Take of pure white wax, and the purest tears of asphaltum, each one ounce, asphalt, half an ounce. The mass, and asphalt having been separately reduced to fine powder, and the wax being melted in an earthenware vessel over the fire, the asphalt is to be added and stirred in and dissolved by stirring; and then the asphalt in like manner. The composition is to be poured out into lukewarm water well kneaded, and then by the hand, into balls about an inch in diameter. These should be kept wrapped round with oiled paper. If white resin be substituted for the asphalt, a clearer composition will be obtained, which answers nearly as well; 2. An asphalt, 1 oz. resin, 1 lb. white wax, being in equal proportions. The etching ground is made by dissolving with heat 4 oz. of resin in 1 oz. of very fine linseed oil, filtering the varnish through a rag, and bottling it for use.

Either of these grounds being applied to the ivory, the figured design is to be traced through it in the usual way, a ledge of wax is to be applied, and the surface is to be then covered with strong sulphuric acid. The effect comes better out with the aid of a little heat; and by replacing the acid, as it becomes diluted, by a fresh portion of moisture, with concentrated oil of vitriol. Simple wax may be employed instead of the copperplate engravers' ground; and strong muriatic acid instead of sulphuric. If an acid solution of silver or gold be used for etching, the design will become purple or black on exposure to sunshine. The wax may be washed away with oil of turpentine. Acid nitrate of silver affords the easiest means of tracing; transient black lines upon ivory.

Ivory may be dyed by using the following prescriptions:—

1. *Black dye*.—If the ivory be laid for several hours in a dilute solution of neutral nitrate of pure silver, with access of light, it will assume a black colour, having a slightly green cast. A still finer and deeper black may be obtained by boiling the ivory for some time in a strained decoction of logwood, and then steeping it in a solution of red sulphate or red acetate of iron.

2. *Blue dye*.—When ivory is kept immersed for a longer or shorter time in a dilute solution of sulphate of indigo (partly saturated with potash), it assumes a blue tint of greater or less intensity.

3. *Open Area*—When a quarry is digging down away from a fault, it takes the inclusion of a *downward* side of the fault from the *down* direction of fault.

The first of these is the fact that the
 Journal of the American Medical Association
 has been the only one of the four
 to publish a special section on the
 subject of "The Medical Profession"
 for many years. This section, which
 is published in the *Journal* of the
 American Medical Association, is
 the only one of the four to publish
 a special section on the subject of
 "The Medical Profession" for many
 years. This section, which is published
 in the *Journal* of the American
 Medical Association, is the only one
 of the four to publish a special
 section on the subject of "The
 Medical Profession" for many years.

5 *Pr* may be given by taking the very first word of the standard time
series as a kind of initial or a measure of the one. In the
case of a continuous process, to perform such a task, if the starting point is
known for a whole number of periods, it will become clear that

[illegible][illegible]

If the living conditions of the very far r. and ivy forest, he found to want a kind of flower is different.

... the ... of ... of ... the ... of ...

"On a recent trip to the great valley of the Congo, I had occasion to be employed as a porter, and, for the first time, was enabled to see the work from a different point of view. The first thing I noticed on the entrance of the valley, was a great number of trees of different extent and gradually taper from the base to the top, some of them at the root; and finally, a capital or irregular in shape. These trees were very rare to so many separate considerations. In cutting a tree, the waste was very enormous, as the only waste should be that arising from the removal of the bark from the saw: even the waste strips of the wood called *chips*, are employed for the making of pen-knives, and many other little things, the scrap and shavings are taken to the manufacture of ivory black, employed for making ink for copying and printing, and other uses, and the clean sawdust and shavings are sometimes used for cooking jelly.

"The methods of dividing the tooth, either into rectangular pieces or into circular discs required for turning, are alike in their early stages, and the same may be resorted to. The ivory saw is stretched in a steel frame to keep it very taut. The blade generally measures from fifteen to thirty inches long, from one to a half to three inches wide, and about the fourth of an inch thick. The tooth is a round coarse, namely, about five or six to the inch, and they are shaped all of round tooth is, between the middle of the common handle with a small thumb nail. The instrument should be very sharp and but slight friction it removes the ground very correctly in entering, and with no more pressure than the weight of the hand. It is and is commonly lubricated with a little lard, tallow, or other animal fat.

"The cutter begins generally at the hollow, and he has found that, although working with the vice, with the curvature upwards, he saws off that part which is too thick for his purpose, and then two or three parallel pieces in the gaps of some of the work, for which the thickness of the tooth at that part is the most suitable; he will then saw off the very wide, firm piece, and afterwards two or three more parallel pieces."

"In measuring the length of every section, he is guided by the graduation of the knee of the timber; having before him the plan or map of his saw works, he will tell the sawyer the billow for the timber work it will take. As the saws are set in the saw for the count, rather than the over, he is careful that the blocks are set off to any required measure, with only a small allowance for the clear butting of the feet, or the space arising from the curved nature of the timber, as is done in the usual practice, as nearly as may be to the imaginary centre of curvature. The waste occurs in cutting up very long pieces, owing to the distance

ence between the straight line and the curve of the tooth, on which account the blocks are rarely cut more than five or six inches long, unless for some special object.

Mr. P. L. Simmonds has given the following as the weights of large elephants' tusks:—

Mr. Gordon Cumming had one weighing	-	-	-	174 lbs.
Mr. Caswood, of Graham's Town, had a pair weighing	-	-	-	330 lbs.
From Camaroon, shipped to Liverpool	-	-	-	184 lbs.
A tusk imported at Rangoon	-	-	-	147 lbs.
At the Great Exhibition of 1851, tusk	-	-	-	102 lbs.

Imports of Ivory in the Years 1856 and 1857.

IVORY BLACK (*Nuit d'ivoire*, Fr.; *Kohle von Elfenbein*, Germ.) is prepared from ivory dust, by calcination, in the very same way as is described under **BLACK**. The calcined matter being ground and levigated on a porphyry slab affords a beautiful velvety black, much used in copperplate printing.

IVORY, FICTILE, is plaster of Paris which has been made to absorb, after drying, melted spermaceti, by capillary action, or it may be prepared according to Mr. Franchi's process as follows:—Master and coloring matter are employed in the proportions of a pound of super-fine plaster of Paris to half an ounce of Indian yellow color. They are intimately mixed by passing them through a fine silk sieve, and a plaster cast is made in the usual way. It is first allowed to dry in the open air, and is then carefully heated in an oven; the plaster cast, when thoroughly dry is soaked for a quarter of an hour in a bath containing equal parts of white wax, spermaceti, and stramon, heated just a little beyond the melting point. The cast on removal is set on edge, that the superfluous composition may drain off, and before it cools, the surface is brushed, with a brush like that known by house painters as a sash tool, to remove any wax which may have settled in the crevices; and finally when the plaster is quite cold, its surface is polished by rubbing it with a tuft of cotton wool.

IVORY NET. Corom, or vegetable ivory. A species of the green pine *Ficus* growing in Central America and Columbia. The *Phytolophus macrocarpa* produces these nuts, which have a structure somewhat resembling that of ivory; but it more nearly resembles white wax. The ivory nut is not used for any important work.

J.

JACK, called also *jack in a box*, and *hand-jack*, is a portable, mechanical instrument, consisting of a rack and pinion, or a pair of claws and ratchet bar, moved by a wheel handle, for raising heavy weights a little way off the ground.

JACK and **JACK-SINKERS**, are parts of a stocking frame. See **HOSIERY**.

JACK-BAK, is the largest jack of the brewer.

JACK, BLACK. The miners' name for the sulphide (sulphuret) of zinc, or blende. See **ZINC**.

JACQUARD. A peculiar and most ingenious mechanism, invented by M. Jac-

quest of I voms to be adapted to work on looms for producing the regular series of draw-boys, or weaving figured cloth. Independence of the ordinary series of warp threads for the formation of the ground of each a web, all those threads which

should rise simultaneously to produce the figure, have their appropriate levers, which a child formerly raised by means of cards, that grouped them together into a system, in the order, and at the time desired by the weaver. This plan evidently required no

little complication in the machine, when the design was richly figured; but the apparatus of Jacquard, which only adds this manoeuvre to a regular mechanical operation, and derives its motion from a simple pedal put in action by the weaver's foot, was generally adopted soon after its invention in 1801. Every common loom is susceptible of receiving this beautiful appendage. It costs in France 200 francs or 8*l.* sterling, and a little more in this country.

Fig. 1043 is a front elevation of this mechanism, supposed to be let down. *Fig. 1046* is a cross section, shown in its highest position. *Fig. 1047*, the same section as the preceding, but seen in its lower position.

A, is the fixed part of the frame, supposed to form a part of the ordinary loom; there are two uprights of wood, with two cross-bars uniting them at their upper ends, and leaving an interval *xy* between them, in place and with the movable frame *n*, vibrating round two fixed points *a*, placed laterally opposite each other, in the middle of the space *xy*, *fig. 1043*.

c is a piece of iron with a peculiar curvature, seen in front, *fig. 1043*, and in profile, *figs. 1046* and *1047*. It is fixed on one side upon the upper cross-bar of the frame *n*, and on the other, to the intermediate cross-bar *b* of the same frame, where it shows an inclined curvilinear space *c*, terminated below by a semi-circle.

v is a square wooden axis, movable upon itself round two brass pivots, fixed into its two ends; which axis occupies the bottom of the movable frame *n*. The four faces of this square axis are pierced with three round, equal, truly-bored holes arranged in a quincunx. The two *a*, *fig. 1043*, are stuck into each face, and correspond to holes *a*, *fig. 1046*, made in the ends which have not their fellow there for the frame; so that in the successive application of the cords to each face of the square axis, the holes pierced in one cord may always fall opposite to those placed in the other.

The right-hand end of the square axis, of which a section is shown in double size, *fig. 1048*, carries two square plates of sheet iron *d*, kept parallel to each other and a little apart, by four spindles *e*, joined oppositely to the corners. This is a kind of lantern, in whose spindles, the hooks of the levers *ff'*, turning round fixed points *yy'* beyond the right hand upright *A*, catch hold, either above or below at the pleasure of the weaver, according as he merely pulls or lets go the cord *z*, during the vibratory movement of the frame *n*.

1048

1049

n is a piece of wood shaped like a T, the stem of which, pointed upwards, passes freely through the cross-bar *b*, and through the upper cross-bar of the frame *n*, which serves as a guide to it. The head of the T piece being applied successively against the two spindles *e*, placed above in horizontal position, first by its weight, and then by the spiral spring *k*, acting from above downwards, keeps the square axis in its position, while it permits it to turn upon itself in the two directions. The same press is given to the assemblage of all the pieces which compose the movable frame *n*.

r is a cross-bar made to move in a vertical direction by means of the lever *a*, in the notches or grooves *i*, formed within the fixed uprights *A*.

n is a piece of bent iron, fixed by one of its ends with a nut and screw, upon the cross-bar *r*, out of the vertical plane of the piece *c*. Its other end carries a friction roller *j*, which, working in the curvilinear space *c* of the piece *c*, forces the, and consequently the frame *n*, to recede from the perpendicular, or to return to it, according as the cross-bar *r* is in the top or bottom of its course, as shown in *figs. 1046* and *1047*.

k, cheeks of sheet iron attached on either side to the cross-bar *r*, which serve as a safe to a kind of claw *h*, composed here of eight small metallic bars, seen in section *figs. 1046* and *1047*, and on a greater scale in *fig. 1049*.

l, upright skewers of iron wire, whose tops bent down hookwise naturally place themselves over the little bars *h*. The bottom of these spindles likewise hooked in the same direction as the upper ones, embraces small wooden bars *l*, whose office is to keep them in their respective places, and to prevent them from twisting round, so that the uppermost hooks may be always directed towards the small metallic bars

space which they occupy. The three links from below are numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

The corresponding vertical skewers, which are raised by the action of the card, are numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

1031

1032

Figure 1031 represents the plan of the upper row of horizontal needles. Figure 1032 is a fragment of the similar chain, formed with perforated cards, which are made to revolve or travel by the motion of the chain. In this movement, all of the perforated cards, whose position, form, and number, are determined by the operation of the loom, comes to be applied in succession against the front face of the square as a or drum, leaving open the corresponding holes, and covering those upon the face of the axis which have no corresponding holes upon the card.

Now let us suppose that the press is let down into the vertical position, shown in Figure 1032; then the card applied against the left face of the axis, being at this or untouched the whole of the horizontal needles (skewers), whose ends are raised to these holes, but pushes back those which are opposite to the unperforated part of the card; thereby the corresponding upright skewers, 3, 5, 6, and 8, for example, pushed out of the perpendicular, unhook themselves from above the bars of the claw, and remain in their place, when this claw comes to be raised by means of the lever *o*, and the skewers 1, 2, 4, and 7, which have remained hooked on, are raised along with the warp threads attached to them. Then by the passage across of a shot of the colour, as well as a shot of the common weft, and a stroke of the lay after shedding the warp and lowering the press, an element or point in the pattern is completed.

The following card, brought round by a quarter revolution of the axis, finds all the needles in their first position, and as it is necessarily perforated differently from the preceding card, it will lift another series of warp threads; and thus in succession for all the other cards, which compose a complete system of a figured pattern.

This machine, complicated in appearance, and which requires some points to be understood, acts however in a very simple manner. Its whole play is dependent upon the movement of the lever *o*, which the weaver himself causes to rise and fall, by means of a peculiar pedal; so that without the aid of any person, after the frame is properly read in and mounted, he can execute the most complex patterns as easily as he could weave plain goods; only attending to the order of his weft yarns, when these happen to be of different colours.

If some warp yarns should happen to break without the weaver observing them, or should be mistaken his coloured shuttle yarns, which would so far destroy the pattern, he must undo his work. For this purpose, he makes use of the lower hooked lever *p*, whose purpose is to make the chain of the card go backwards, while working the loom as usual, withdrawing at each stroke the shot both of the ground and of the figure. The weaver is the more subject to make mistakes, as the figured side of the web is downwards, and it is only with the aid of a bit of looking-glass that he takes a peep of his work from time to time. The upper surface exhibits merely loose threads in dif-

fixed points, according as the pattern requires them to be upon the one side or the other.

It must be evident, that such a number of paste-boards are to be provided and mounted as equal the number of the warps of the shuttle loom in the beginning and end of any figure or design which is to be woven; the piercing of each paste-board individually will depend upon the arrangement of the lifting rods, and their connection with the warp, which is according to the design and option of the workman; great care must be taken that the holes come exactly opposite to the ends of the needles; for this purpose two large holes are made at the ends of the paste-boards, which fall upon central points, by which means they are made to register correctly.

It will be hence seen, that, according to the length of the figure, so must be the number of paste-boards, which may be readily displaced so as to remove and produce the figure in a few minutes, or remove it, or replace it, or preserve the figure for future use. The machine, of course, will be understood to consist of many sets of the lifting rods and needles, shown in the diagram, as will be perceived by observing the disposition of the holes in the paste-board; those holes in order that they may be accurately distributed, are to be pierced from a gauge, so that not the slightest variation shall take place.

To form these cards, an ingenious apparatus is employed, by which the proper steel punches required for the piercing of each distinct card, are placed in their relative stations preparatory to the operation of piercing, and also by its means a card may be punched with any number of holes at once. This disposition of the punches is effected by means of rods connected by cords disposed in a frame, in the nature of a false loom, on which the pattern of the work to be performed is first read in.

These improved pierced cards, or paste-boards, apply to a weaving apparatus, which is so arranged that a figure to be wrought can be extended to any distance along the loom, and by that means the loom is rendered capable of producing broad figured works; having the long lever *q* placed in such a situation that it affords power to the foot of the weaver, and by this means enables him to draw the heaviest monitures and figured works, without the assistance of a draw-boy.

The machinery for arranging the punches consists of a frame with four upright standards and cross-pieces, which contains a series of endless cords passing under a wooden roller at bottom, and over pulleys at the top. These pulleys are mounted on axles in two frames, placed equally over the top of the standard frame, which pulley-frames constitute the table commonly used by weavers.

In order better to explain this endless cord, *fig. 1* & *2* represent a single endless cord, *1 1*, which is here shown in operation, and part of another endless cord, *2 2*, shown stationary. There must be as many endless cords in this frame as needles in the weaving loom. *a* is the wooden cylinder, revolving upon its axis at the lower part of the standards; *b*, the two pulleys of the pulley-frame above, over which the individual endless cord passes; *c*, a small transverse rod. To each of these rods a weight is suspended by a single thread, for the purpose of giving tension to the endless cord. *d* is a board resembling a common comb-bar, which is supported by the cross-bars of the standard frame, and is pierced with holes, in situation and number corresponding with the perpendicular threads that pass through them; which board keeps the threads distinct from each other.

At *e*, the endless cord passes through the eyes of wires resembling needles, which are contained in a wooden box placed in front of the machine, and shown in this figure in section only. These wires are called the *punch-projectors*; they are guided and supported by horizontal rods and vertical pins, the latter of which pass through loops formed at the hinder part of the respective wires. At *f* are two horizontal rods extending the whole width of the machine, for the purpose of producing the cross in the cord; *g* is a thick brass plate, extending along in front of the machine, and lying close to the box which holds the *punch-projectors*; this plate *g*, shown also in section, is called the *punch-ladder*; it contains the same number of apertures as there are *punch-projectors*, and disposed so as to correspond with each other. In each of these apertures, there is a punch for the purpose of piercing the cards, slips, or pasteboards

with holes. *A* is a thick metal plate of the same diameter, and shown in figure 1, carrying long also in its number of apertures, and their disposition, with the punch-receiver, and the punch-holder. The plate *A*, is called the punch-receiver.

The manner of its application is to transfer each of the punches in order by placing upon the individual card from the punch-holder *B*, but the punch-receiver *A*, when they will be properly arranged, and ready for passing the individual card or slip, with each hole as above described in upon the machine, and are prepared for forming the way chords in the holes in the block, when this part is brought against the ends of the needles. The manner of attaching the patterns to the punches will be effected in the following manner.

The punches are to be read in accordance to the primary series, as in a silver sample, upon the machine, first below the hole *f*, and passed under the revolving working cylinder *C*, as explained before for a series in front of the machine, to reach the cylinder *E*. He then takes the upper thread of the primary series, the lower, and draws them forward, so as to draw a card behind the machine thus arranged, as shown by line, for the purpose of keeping them separate from the cards which are not intended to be printed upon. All the punches, however, which are connected with the cards brought forward will be thus made to pass through the corresponding apertures of the punch-holder, and up the cords will project the punches out of those apertures, the corresponding apertures of the punch-receiver *A*. The punches will now be properly arranged for passing the required holes in a card or slip, which is to be effected in the following manner.

Remove the punch-receiver from the front of the machine, and having placed one of the slips of card or parchment between the two sliding plates of metal, completely pierced with holes corresponding to the points of the holes, by the punch-receiver upon these perforated plates; to which it must be made to fit by screws and locks, the sliding parts of the punch-holder being drawn back. Upon the back of the punch-receiver is then to be placed a plate or block, coated with preparation of gum, corresponding to the above described holes, upon which the punch will fall. The plates and the blocks thus laid together, are to be pushed under a press, by which means the part of the blocks will be made to pass through the apertures of the punch-receiver, and wherever the punch has been deposited in the receiver by the above process, the card punches will be forced through the slip of parchment, and pierced with each letter as are required for producing the figured design in the lower.

With each of the cards, the punch-receiver is returned to its place in front of the machine, and all the punches forced back into the apertures of the punch-holder as at first. The next set of cards is now drawn forward by the next hand, as above described, which sends out the punch-propagator, as before, and brings the punches in the punch-receiver, ready for the operation of piercing the next card. The process being thus repeated, the whole pattern is, by a number of operations, transferred to the punches, and afterwards to the cards or slips, as above described.

JADE, *axe-stone* (*Nephrite*, *Ceramide*, Fr.; *Halstein*, Germ.) is a mineral of a greenish, bluish, or whitish colour, compact, and of a fatty luster. Spec. grav. 2.95; scratches glass; is very tough; fuses into a white enamel. It comes from China, and has been found in Australia; it is used among rude nations for making hatchets, and is susceptible of being cut into any form. In China the jade is greatly valued, especially the pure white varieties. These are worked into cups, and as ornaments for the Josses, or emblem of power.

The composition of Jade, as given by Klaproth and Rosenschlag, is —

Silica	-	-	-	-	50.50	-	-	24.00
Magnesia	-	-	-	-	31.00	-	-	2.00

JAPAN EARTH; *Terra Japonica*. See GLAZING.

JAPANNING is a kind of varnishing or lacquering, practised with excellence by the Japanese, whence the name.

The only difference between varnishing and Japanning is that after the application of every coat of colour or varnish, the object so varnished is placed in an oven or stove at as high a temperature as can safely be employed without injuring the articles or causing the varnish to blister or rot.

For black japanned works, the ground is first prepared with a coating of black, made by mixing brown ivory black to a proper consistency with dark red ochre varnish, as this gives a blacker surface than could be produced by Japan alone. If

the surface is required to be polished, five or six coats of japan are necessary to give sufficient body to prevent the japan from being rubbed through in polishing.

Coloured japans are made by mixing with the hard varnishes the required colour, and proceeding as described. See VARNISH.

JARGOON, the name given to a variety of Zircon from Ceylon. It is seldom perfectly transparent, and is either colourless or grey, with tinge of green, blue, red, and yellow of various shades, but generally smoky and ill-defined. It occurs in worn angular pieces, or in small detached crystals, rarely exceeding 6 or 8 carats in weight, chiefly in the mud of a river in Ceylon. The surfaces of the crystals are smooth, and possess a lustre more nearly approaching that of the diamond than any other gem. At the present day, though out of fashion and in no request, it is still occasionally sold for inferior diamonds.

Davy says that the light grey varieties of the zircon are sold by the inhabitants of Ceylon as imperfect diamonds, the natives being altogether ignorant of the true nature of the mineral. It is most abundant in the district of Matara, whence it has its common name in Ceylon of *Matara diamond*. The colourless zircon is also cut and sold as a false diamond in the bazaars of India. — H. W. R.

JASPER (*Jaspe rubicundus*, Fr.; *Jasper*, Germ.) is a sub-species of quartz, of which there are five varieties. 1. The Egyptian red and brown, forming nodules with ring or tunnel-shaped depressures. 2. Striped jasper, or clay altered by heat, and differing from true jasper by being fusible on the edges, before the blowpipe. 3. Porcelain riband or jasper. 4. Common jasper. 5. Agate jasper. The prettiest specimens are cut for seals, and for the inferior kinds of jewellery ornaments. See LAPIDARY. — H. W. R.

JATROPHA MANIHOT. A plant belonging to the Euphorbiaceæ, from which the *Cassava meal* is prepared, and from the express juice of which is obtained *Cassava starch* and *Tapioca*. See TAPIOCA.

JEAN. A twisted cotton, usually striped. Satin-jans are woven so as to present a smooth glossy appearance. It is used for stays, &c.

JELLY, ANIMAL. See GELATIN, GLUE, and ISINGLASS.

JELLY, VEGETABLE. A great many vegetable productions yield upon infusion or decoction gelatinous solutions. These vary very much in character. The jelly of ripe currants and other berries, is a compound of mucilage and acid, which loses its power of gelatinising by prolonged ebullition.

JESSAMINE or **JASMINE**. A well-known family of plants. The *Jasminum fruticans*, a native of the southern parts of France, *J. odoratissimum*, a native of India, and *J. semibre*, a native of India and Arabia, are used to obtain the essential oil of jasmine. See PERFUMERY.

JET (*Jais*, or *jais*, Fr.) Jet occurs in the upper lias shale in the neighbourhood of Whitby, in Yorkshire, in which locality this very beautiful substance has been worked for many hundred years. The jet miner searches with great care the clayey rocks, and finding the jet spread out, often in extreme thinness between the laminations of the rock, he follows it with great care, and frequently he is rewarded by its thickening out to two or three inches.

The best jet is obtained from a lower bed of the upper lias formations. This bed has an average thickness of about 20 feet, and is known as jet rock. An inferior kind, known as soft jet, is obtained from the upper part of the upper lias, and from the sandstone and shale above it. The production of jet in this country appears to be limited to the coast of Yorkshire, from about nine miles south of Whitby to Honthly, about the same distance to the north; the estates of Lord Moulgrave being especially productive. There is a curious allusion to this in Drayton's *Polyolbion*.

- The rocks by Moulgrave, too, my glories forth in set,
Out of their crinated rocks can give you perfect jet.

Dr. Young, in his *Geology of the Yorkshire Coast*, writes—"Jet, which occurs here in considerable quantities in the aluminous bed, may be properly classed with fossil wood, as it appears to be wood in a high state of bituminisation. Pieces of wood impregnated with silica are often found completely crusted with a coat of jet about an inch thick. But the most common form in which the jet occurs is in compact masses of from half an inch to two inches thick, from three to eighteen inches broad, and of ten or twelve feet long. The outer surface is always marked with longitudinal striae, like the grain of wood, and the transverse fracture, which is conchoidal, and has a resinous lustre, displays the annual growth in compressed elliptical zones. Many have supposed this substance to be indurated petroleum, or animal pitch; but the facts now quoted are sufficient to prove its ligneous origin."

It does not appear to us that the "ligneous origin" of jet is by any means established; indeed we think the amount of evidence is against it. There is no example as far as we can learn, of any discovery of true jet having a strictly ligneous structure, or showing

a strong idea the conversion of wood into the coal-like substance. There is, indeed, however, in a few localities, evidence in the other veins of those who have written on the subject. Mr. Simpson, the talented curator of the Whitty museum, has been much attracted to the subject, and says, "Jet is generally considered to have been a wood, and in some cases it undoubtedly has been so; for the woody structure often remains, and it is not unlikely that fossilized vegetable matter may have been changed into jet. But it is evident that vegetable matter is not an essential part of jet, for we frequently find the bones, and the entire skeletons of some large extinct jet. In the Whitty Museum there is a large mass of bone, which had the external contour of a jet for a size a quarter of an inch in thickness. The jetty matter appears to have first covered the pores of the bone, and there is here laminated, and during the subsequent process, the whole bony matter has been gradually deposited, and the place occupied by jet is not to preserve its original form." After an attentive examination of this specimen, we are not disposed to agree entirely with Mr. Simpson.

Jet certainly occurs in a mass which has undergone the conversion of a bone, but we think a chemical examination of such a mass, we think, however, rather, says it was bone. Wood without doubt has been found encrusted with jet, no fragments of animal matter may also have been found, but this is not consistent with our knowledge of geological and chemical changes, to suppose that both animal and vegetable matter would undergo the change. By process of substitution, we know that silica will take the place occupied by carbon, or woody matter, as, for example, in the fossil palms of Trinidad, and the fossilized forests of Egypt, but we have no example within the entire range of the coal formations of the world of carbon taking the place of any of the earth.

Jet is found in plates, which are sometimes perforated by tubular pores. Mr. Ripley, of Whitby, has several curious examples, - two pieces of jet, in the one case having within quartz pebbles, and in another jet partially covered by a regular fragment of quartz rock. "This is the more remarkable," says Mr. Ripley, "no quartz rock, or, indeed, any other sort of rocky fragment, is rarely found in the upper jet."

The very fact that we find jet encrusting broken bones, and other fragments of stone, and investing wood, seems to show, that a liquid, or at all events, a gaseous condition, must at one time have prevailed. We have existing evidence of this. Dr. Yocum, in the work already quoted, says - "In the cavities of scapulae containing perfect ones, we sometimes meet with petrified wood, and of which first exposed, it is usually quite fluid and of a dark green color; but it soon becomes solid and black, and at last hardens into a kind of pitch, which gradually becomes with heat, and when heated burns with a crackling noise, and emits a strong resinous smell." One more example of evidence in favor of the view that jet has been formed from wood. It is cited (*Reed's Illustrated Guide to Wharfedale*) that in front of the gate-work of Harbours Wyke existed a petrified stump of a tree, in an erect position, three feet high, and fifteen inches across, having the roots of coaly jet in a bed of sand; whilst the trunk in the sandstone was partly petrified, and partly of decayed woody wood. Even in this example it would appear, that after all, a coating of jet was all that really existed upon this example of the equisetum, which probably would have been it grew. Mr. Simpson, in a valuable little publication, "*The Plants of the Yorkshire Lias described from Nature, with a short Outline of the Geology of the Yorkshire Coast*," says - "From all we know respecting this beautiful mineral, it appears extremely probable that it has its origin in a certain lustrous matter, or petroleum, which abundantly impregnates the jet-rock; giving out a strong odour when it is exposed to the air. It is frequently found in a liquid state in the chambers of an ammonite and belemnites and other cavities, and, whilst the ammonite operator is breaking a liss nodule, it flies out and stains his garment. This petroleum, or mineral oil, also occurs in nodules which contain no organic remains, and I have been informed by an experienced jet miner that such nodules are often associated with a good store of jet, and are therefore regarded as an omen of success."

Jet is supposed to have been worked in this country long before the time of the Danes in England, for the Romans certainly used jet for ornamental purposes. Lionel Charlton, in the history of Whitby, says, that he found the ear-ring of a lady having the form of a heart, with a hole in the upper end for suspension from the ear, it was found in one of the Roman tumuli, lying close to the jaw bone. There exists no doubt that when the abbey of Whitby was the seat of learning and the resort of pilgrims, jet rosaries and crosses were common. The manufacture was carried on till the time of Elizabeth, when it seems to have ceased suddenly, and was not resumed till the year 1800, when Robert Jefferies, a painter, and John Carter made beads and crosses with files and knives - a neck guard, made in this manner, fetched one guinea. A stranger coming to Whitby saw them working in this rude way, and advised them to try to turn it; they followed his advice and found it answer; several more then joined them, and

the trade has been gradually increasing. Most of the best jet ornaments are sent to London, the inferior ones are mostly purchased for the American market.

The jet workers compose of the great variety of designs in jet. Several designs have been sent them, but the artists not being acquainted with the peculiarities of the material, their designs are not generally applicable, and the most successful is much more successful in the imitation of natural objects than any artificial ornamentation.

JEWELLERY. See GOLD and SILVER.

JIGGING, a mining term. Separating the ore with a griddle, or wire-worked sieve, the heavier substances passing through to the bottom or lower part of the sieve, the lighter substances remaining on the upper part.

JINTA WAN. A substance somewhat resembling gutta serena, imported from India.

JUJU BE. The fruit of the *J. paphu vulgaris* and *J. jujube*, about the size of and nearly resembling a small plum. The French confecturers prepare a marmalade from the juice of the fruit, but nearly all the jujubes sold by our druggists and confectioners are merely dried mucilage, flavoured and sweetened.

JUMPER, a mining term. A large borer, steaked at each end like chisel. It is worked by the hand.

JUNIPER. A genus of plants belonging to the order *Celastræ*. About twenty species are known. This plant is cultivated mostly for its berries, which, when distilled with water, yield a valuable essential oil. The berries are largely employed in the manufacture of brandies and gin. The French name of the plant is *Genévre*, and hence our English words "gin" and "genève."

The *Juniperus Bernandina*, the Bermuda red cedar, is a large tree with soft and fragrant wood, and is what is used in making pencils, and by cabinet makers. See CEDAR.

JUTE consists of the fibres of two plants, called the clunch and rebound (*Corchorus edulis* and *Corchorus pepularis*), extensively cultivated in Bengal, and forming, in fact, the material of which gunny bags and gunny cloth are made. It is nearly, though not quite so high, a price as cotton. See COTTON. It comes into competition with flax, tow, and cordilla, in the manufacture of stair and other carpets, bagging for cotton and other goods, and such like fabrics, being extensively used for these purposes in Dundee. But it is unsuitable for cordage or other articles into which hemp is much required, from its snapping when twisted, and rotting in water. — M. CHALK.

K.

KAHOK. A name for a clay ironstone in Ceylon. — *Sinimoda*.

KAL. "Will iron; a coarse, false kind of iron" (*He-haw*). A mining term. In the East, in Cornwall, a *Kal* is a hole containing much iron.

KALEIDOPHON. An instrument devised by Prof. Wheatstone. An elastic bar is fixed by one of its extremities, and at its free end it carries a silvered or polished plate; a ray of light is reflected from the plate, and when the plate is put in vibration, the free point of light describes various curves, corresponding with the musical notes produced by the vibrations.

KALEIDOSCOPE. A well-known instrument invented by Sir David Brewster. It has been much employed in arts of design. The leading conditions are that the angle at which the reflectors are placed is a submultiple of 360°, that the only positions in which a body can be placed to form perfectly symmetrical images are between the ends of the mirrors, or in contact with the ends, and the eye must be as near as possible to the angular point.

KALI. The Arabs gave this name to an annual plant which grows near the seashore; now known under the name of *Salicola soda*, and from whose ashes they extracted a substance, which they called *alkali*, for making soap. The term *alkali* is used by German chemists to denote caustic potash, and *kalium*, its metallic basis; instead of our potash and potassium.

KANGAROO. A marsupial animal, native of Australia. Its tail makes excellent soap, and its skin, when tanned, becomes a soft and durable leather.

KAO LIN. *Terra à porcelaine*, Fr.; *Porcellanerde*, Germ.) is the name given by the Chinese to the fine white clay with which they fabricate the biscuit of their porcelains. See CLAY and PORCELAIN CLAY.

KARABE, a name of amber, of Arabic origin, in use upon the Continent.

KARN. A Cornish miner's term, frequently, according to Borlase, used to signify the solid rock; — more commonly a pile of rocks.

KAHSTLITE. The name given by Haas to anhydrous sulphate of lime.

KATTIMUNDUO or **CHITTEMUNDUO.** A caoutchouc-like substance obtained from the *Euphorbia antiquorum* of Roxburgh. It was first exhibited in this country in the Great Exhibition of 1851, being sent by Mr. W. Elliott from Singapore.

It was of a dark brown colour, opaque except in thin pieces, hard and somewhat

beats a common temperature, but easily colored by heat. Perhaps suitable for staining wool, and becoming as vivid, and remarkably sticky and adhesive for fastening, resembling in a great measure charcoal.

It is said to be used for staining wood, following *Leichtenstein*, &c.

KITEE, ANCHOR. A small anchor with an iron shank and two wings.

KUTTER. A vessel or boat, by sea and others at the Ionian and Northern Islands.

KYE. A cold mountain fire stream.

KYVE. A deep river. A large channel in Denmark carries also a beaver's form for a mill race.

KEIL. A wheel used in turning millstones, &c. See *WHEEL*.

KIEP (Pers., *P. Hissid*, *Gomez*) is the upper stratum of the earth produced by the action of various kinds of heat or action. They are not more strictly the rocks in the common sense, than just their nature, with much stirring of the pure soil. Dr. Frey analysed many specimens of kiep, and found the quantity of soluble matter in 100 parts of the soil to be from 40 to 50, while the insoluble was from 47 to 53. The soluble consisted of—

Sulphate of soda	44	100
Sulphate of lime and potash	33	40
Magnesium of soda and potash	23	27
The soluble matter consisted of—	100	100
Carbonate of lime	240	100
Soda	60	100
Alumina mixed with iron oxide	50	100
Sulphate of lime	60	100
Sulphate and lime	20	100
	1000	1000

The best of these specimens was from Harker, the second from Rome, Italy, &c. The kiep is a property of the Mediterranean. It is found in many places, and is a very variable composition, and hence it was very apt to produce an incorrect result, when employed as the chief analysis of a specimen, which it was for a very long period. The *Pinus maritima* and *Pinus sylvestris* are found to afford the best kiep by decomposition, but all the kiep yield a better product when they are of two or three years growth than when cut younger. The kiep yields on the whole a very variable amount of no carbonate of soda, but much of soda and potash, and a small quantity of potash, chloride of sodium, iodide of potassium, and chloride of potassium. The composition of the soluble salts being according to M. Gay Lussac, 24 of carbonate of sodium, 25 of chloride of potassium, and a little sulphate of potash. The very low price at which soda ash, the dry crude carbonate from the decomposition of sea salt, is now sold, has nearly superseded the use of kiep, and round red is manifestly utterly unprofitable. When the common sea wash, commonly used for producing kiep, is incinerated in a closed crucible it gives a charcoal termed *charbon éthiops*.

KERMES GRAINS, ALKERMES, are the dried bodies of the female insects of the species *Coccus*, which lives upon the leaves of the *Quercus ilex* (prickly oak), *Kirby* and *Spence*, and also *Staphylinus*, state that the *Coccus* is found on the *Quercus coccinea*. The word *kermes* is Arabic, and signifies little worm. In the middle ages, this dye stuff was therefore, called *cochenille* in Latin, and *carmin* and *carminum* in French. It is curious to consider how the name *carmin* has been since transferred to red sulphur of mercury.

Kermes has been known to the Egyptians the days of Moses; it has been employed from time immemorial in India to dye silk; and was used also by the ancient Greek and Roman dyers. Pliny speaks of it under the name of *cochenille*, and says that there grow upon the oak in Africa, Sicily, &c., a small excrements like a bead, called *cuscutum*; that the Spaniards paid with these grains half of their tribute to the Romans; that those produced in Sicily were the worst; that they served to dye purple, and that those from the neighbourhood of Emera in Lusitania (Portugal) were the best.

In Germany, during the ninth, twelfth, thirteenth, and fourteenth centuries, the rural serfs were bound to deliver annually to the convents a certain quantity of *kermes*, the *Coccus palmarum*, among the other products of husbandry. It was collected from the trees upon St. John's day, between eleven o'clock and noon, with religious ceremony, and was therefore called *John's blood* (St. John's blood), as the Germans call it. At the above period, a great deal of the German *kermes* was consumed in Venice, for dyeing the scarlet to which that city gives its name. After the discovery of American cochineal having been introduced, began to supersede *kermes* for all brilliant red dye.

The principal varieties of kermes are the *Coccus quercus*, the *Coccus palmarum*, the *Coccus fragarie*, and the *Coccus rosae*.

The *Coccus quercus* insect lives in the bark of the *Quercus* oak. The female lays an egg, in the end of a small peg, of a brown-red colour, and is covered with a white dust. From the middle of May to the middle of June the eggs are collected, and exposed to the vapour of vinegar, to prevent their incubation. A portion of time is left upon the tree for the incubation of the breed. In the department of the Landes, in France, one half of the kermes crop is dried.

The kermes of Poland, or *Coccus palmarum*, is found upon the roots of the *Scleranthus perennans* and the *Scleranthus annuus*, in a sandy soil of that country and the Ukraine. This species has the same properties as the preceding; one pound of it according to Wolff being capable of dyeing 10 pounds of wool, but Hermstedt could not obtain a fine colour, although he employed 5 times as much of it as of cochineal. The Turks, Armenians, and Cossacks dye with kermes their Morocco leather, cloth, &c., as well as the houses and tents of their houses.

The kermes called *Coccus fragarie* is found principally in Sicily, upon the root of the strawberry.

The *Coccus rosae* was used by the Jews of the Polish kermes, and dyes with alum a fine red. It occurs in Russia.

Kermes is found not only upon the *Ilex aquifolium* in the Ukraine, but upon a great many other plants.

Several kermes is purplish, of a deep red colour, of an agreeable taste, and a rough and pungent touch. Its colouring matter is soluble in water and alcohol; it becomes yellowish or brownish with acids, and violet or crimson with alkalis. Sulphate of iron blackens it. With alum it dyes a bluish red, with copperas, an agreeable grey with sulphate of copper and tartar, an agreeable green; with tartar and oil of turpentine, a yellowish, with iron alum and tartar, a black with sulphate of zinc and tartar, a violet. Scarlet and crimson dyed with kermes were called *grain colours*. The red eggs for the Levant are dyed at Orleans with equal parts of kermes and madder, and occasionally with an addition of Brazil wood. Kermes is but little used in England at present as a dyeing substance.

KERMES MINERAL. Pure mineral kermes is regarded by Berzelius, Fuchs, and Rose, as an arsenical ternary phosuret of antimony. As the preparation has no use in the arts or manufactures, for its mode of preparation and its chemical constitution we refer to *Ure's Dictionary of Chemistry*.

KERSHETZITE. Red antimony ore, composed of oxygen, 57.1; antimony, 34.45 (Ann. Chem., 20:17).

KIRSEY. A coarse stuff woven from long wool, chiefly manufactured in the north of England.

KIRSEYMER. Coarsely spun cotton yarn. A fine fabric woven plain from the finest wool, a manufacture of the west of England principally.

KHAYA. One of the largest and handsomest trees growing on the western coast of Africa. The wood is of fine quality, and of a reddish colour like mahogany.

KIADOGGA WOOD, called also *Asiayan wood*. This wood is said to be the extreme or hurr of the *Fraxinus excelsior*, or of the *Fraxinus* drawn from the Malabar, the Island of Borneo, Amboyna, &c.

KILN, F. a mining term. A building usually made of iron, in which the ore is drawn to the surface from the depths of the mine.

KILNAS. The name given by the Cornish miners to the *slaty slate* of that district. It varies very much in colour and character, being sometimes of a clay-white, and at other times gray or blue. It is in one district soft; in another, compact and hard. According to the character of this rock, the miner determines on the probability of the mineral veins which traverse it being metalliferous or the contrary.

KILN (*Furn.*, Fr.; *Ofen*, Germ.) is the name given to various kinds of furnaces and stoves, by which an attenuated heat may be applied to bodies; thus there are brick-kilns, hop-kilns, lime-kilns, salt-kilns, pottery-kilns. See BRICK, LIMESTONE, MALT, POTTERY, for a description of their respective kilns.

KIMERIDGE CLAY. The strata which underlie the Portland Stone of Dorsetshire, and the south-west of England, are based upon a considerable thickness of dark brownish or bluish-gray clay, to which the term Kimeridge Clay has been given by geologists, from the circumstance of its being largely developed and well displayed in the neighbourhood of the village of that name.

Throughout the life of Purbeck, but especially in the part of it in question, the clay assumes a very shaly and laminous character, sometimes passing into more massive beds of brownish shaly coal, possessing a conchoidal fracture.

The Romans, and also the Celts who inhabited the country previously to its invasion by the former nation, appear to have manufactured the harder portions of the

shale was capped and below arranged, first, clayey into fossil, argillaceous, and siliceous, specimens of which last have been found in the neighbourhood of Wareham, in Dorsetshire, and resembling the warts of *Ekmania*.

Considerable shale about the size of a penny piece, have now been dug up in good quantities in this part of the Isle of Purbeck, as many as six being open and broken down, found usually perfect and clear.

Author also has been much devoted in respect as to the origin and use of these carbonaceous shale, by some they are supposed to have passed current as timber, or where where the name of Kimeridge has been used, by which they are commonly known, has been applied to them; but, the most probable supposition is, that they were the portions of the mineral shell to the hollow, and left adhering to it after the animal or other elements in a similar disposition had been turned from their former circumstances, and that at some subsequent period these hollow pieces of the former were worn at *Ammonia* or *Chama* by the weathering.

The shale around Kimeridge contains a number of animal and vegetable remains the former consisting of the shells of *Nautilus*, *Ammonia*, &c., together with the bones and teeth of large animals and fish; while the latter is in so easily divided a state as not to be distinguishable to the eye. Much carbonate of lime and pyrites are also present, especially in those portions in which animal remains are most abundant.

The variation in the external character of the shale is accompanied by a corresponding variation in the relative proportions of mineral and organic matter contained in it; thus portions which are the most fossiliferous contain a large proportion of mineral matter combined with a relatively small proportion of organic matter, while on the other hand, in the harder and more massive portions which break with a conchoidal fracture, the organic matter is greatly in excess of the mineral matter, as is shown by the following analysis.

	Analysis of the shale, determined by the following methods		
	A	B	C
Amount of volatile matter	18.51	32.5	73.4
" " mineral matter	81.49	67.5	26.7
	100.00	100.0	100.0

When heated the shale gives off copious fumes of a dark greenish color resembling that of petroleum; and when ignited, it burns of itself with a dull smoky flame, leaving, when freely exposed to the atmosphere, a reddish ash, which generally retains the form of the original fragment.

The shale has long been used for fuel by the people of the district where it occurs, and the ashes left after combustion have long been known to the farmers on the coast to exercise a beneficial influence upon their crops, especially turnips; but the unpleasant smell given out by it when burning has prevented it from being used except by the poorer inhabitants.

Within the last few years works were established at Wareham, for the purpose of extracting naphtha and other products from the shale by distillation; but the manufacture was abandoned in consequence of the impossibility of destroying the smell given out by the naphtha.

This defect having now, it is believed, been overcome, the works have lately been re-opened, and are now being carried on with every prospect of success.

The chemical composition and properties of the shale have been recently thoroughly investigated by Dr. Hofmann, of the Government School of Mines.

The following results were obtained by him from the distillation of the shale, at a high temperature, for the purpose of producing gas:—

Amount of gas, water, ammonia, &c.	63.5
Amount of coke	36.5—100.0

The shale distilled in a gas retort furnished a gas composed of—

Olefiant gas and congeners	8.4
Light carbonated hydrogen and hydrogen	60.3
Carbonic oxide	9.7
Carbonic acid	8.2
Sulphuretted hydrogen	7.0—100.0

The composition of this gas, freed from carbonic acid and sulphuretted hydrogen, by passing through an ordinary lime purifier, was as follows:—

Flammable gas and vapours	100
Light carbonated hydrogen and hydrogen	79.0
Carbonic oxide	11.0—100.0

The composition of the coke produced was:—

Carbon	73.4	72.8
Ash	24.8	20.3
	107.7	100.0

The excess above 100 arises from the presence of sulphides in the coal, which during the process of incineration absorb oxygen and are converted into sulphates.

A ton of shale furnished 11,200 cubic feet of this purified gas, the illuminating power of which, used in an argand burner, consuming 5 cubic feet per hour, equalled that of 20 sperm candles, while the percentage of coke remaining was 6.5.

The liquid and solid products obtained by the distillation of the shale at a low temperature, are an effluve, consisting, dark brown oil, suspended in an aqueous liquid, charged with sulphuretted hydrogen, carbonic acid, and ammonia.

This oil, purified and distilled with water, furnishes an oily liquid heavier than water; a tar-like residue being left in the retort.

The oily liquid which, when purified, gives out the colour of the finest varieties of coal-tar naphtha, is a mixture of several chemical substances.

When treated with concentrated nitric acid, this oily liquid is divided into two portions, one of which is dissolved by the acid, while the other insoluble portion floats on the surface of the solution in the form of a light colourless oily liquid, resembling in its general character the hydrocarbons of Boghead coal-tar oil, and of petroleum. The nitric solution which forms the larger proportion of the oily liquid, when mixed with water, furnishes a dense, heavy, yellowish oil, with the odour of nitrobenzol.

Hence it appears that the oily liquid obtained by the distillation of the shale consists chiefly of benzol and its homologues, mixed with small quantities of petroleum hydrocarbons. When sufficiently purified it is applicable for all the purposes for which benzol is employed, for dissolving india-rubber and gutta-percha, for removing stains from fabrics, for preparing varnishes, for making artificial oil of almonds, &c.

On submitting to distillation without water, and at a rather high temperature, the only tar-like residue remaining in the retort after the crude volatile liquid obtained by heat from the shale had been distilled with water, other volatile products are obtained.

The first portion of the oil obtained during the distillation is of an amber colour when first distilled, and much less limpid than the oil produced by distillation with water. It also possesses an offensive sulphurous smell, which however is lost on exposure to the air, while the oil assumes a much darker colour. This oil is acted upon by sulphuric, nitric, and hydrochloric acids, by which, especially by the first, a portion of it is resinified.

The remaining portion of the oil, when washed with water and afterwards distilled with steam, furnishes a perfectly colourless oil with the properties of paraffine. This last oil, which forms but a small fraction of the original oil, behaves in all respects like the paraffine oil obtained from Boghead canal coal, and is applicable to the lubrication of machinery, and all the other purposes to which that liquid is applied.

The black, pitch-like, coky residue left in the retort resembles in general character the coke produced from coal in the manufacture of gas.

The ash of the incinerated coke contains nearly the same proportions of silica, alumina, and iron as Portland cement. The following is an analysis of the ash left by the shale which contains the larger amounts of mineral matter:—

	Ash of Kimberidge shale.	Portland cement.
Insoluble residue	22.01	
Peroxide of iron	7.10	5.30
Silica	21.73	23.23
Alumina	10.60	7.73
Lime	20.62	54.11
Carbonic acid	20.92	2.15

100.00

The composition of the shale at 4 for the manufacture, for the purpose of obtaining the liquid and solid products, furnished the following results:—

Analysis of A.

Coke	71.5	{	Mucous matter . . .	74.1
			Carbon	80.0
			Hydrogen	2.6
			Light oil (volatile) . .	3.7
Oil and solid prod- ucts	14.5	{	Heavy oil (residue) . .	1.9
			per cent. of paraffine .	5.3
			Residue of pitch . . .	7.4
			Oil, water, &c.	1.7
Gas, water, &c. . .	13.5			
	100.0			100.0

Analysis of B.

Coke	43.0	{	Mucous matter . . .	82.2
			Carbon	10.2
Oil and solid vol- atile products	5.0	{	Light oil (volatile) . .	3.7

Gas, water, &c.	18.0	{	Gas, water, &c.	18.0
	<hr/> 100.0			<hr/> 100.0

The manufacture of the shale at Westport, according to Mr John C. Shand, is conducted in the following manner:—

The retorts are charged with about 3 wt. of shale, previously broken down into about two inches square, and the temperature is maintained as nearly uniform as possible. In order to obtain the required uniform temperature the retorts are constructed so as to have banks of masonry built. The gas issued in the retorts is then conducted by means of a leaden pipe, and the product is a crude oil; there is a quantity of gas made during the operation, which is not condensed, but used for ordinary purposes. The crude oil is allowed to stand in long cisterns of lead for the purpose of letting the mineral water (of which there is a large quantity) settle. The oil is then put into a still, and rectified once or twice at the steam bath. The first product is a light oil, making over-proof 75; the next products are kerosene, containing paraffine, which is now in great request by manufacturers.

The shale, on being taken out of the retorts, is placed in chise vessels, and when cool is ground in a mill for manure. In its natural state the shale is not sufficiently rich in ammonia for this purpose; but at this stage the artificial manure is as valuable as Ichaboe guano, both having been recently analysed for the purpose of comparison. By keeping the temperature low in the retorts neither the phosphorus nor the organic matter are destroyed.

The name has been changed from Kimeridge shale to South Highland coal by the manufacturers, the failure of the late company (by whom the former designation was used) having, it was considered, rendered the statement expensive. The term South Highland coal was selected from the resemblance to the Highland coal of Scotland, now so extensively worked near Edinburgh.—H. W. R.

KING WOOD is imported from the Brazils, and is sometimes called violet wood. This is one of the most beautiful of the hard woods, and is used in small cabinet work.

KINIC ACID. A peculiar acid extracted by Vauquelin from cinchona.

KINO is an extract obtained most probably from the *Platanus orientalis*, which grows on the Malabar coast. In India, also it is used for dying cotton a nashken colour. It is of a reddish-brown colour, has a bitter styptic taste, and consists of tannin and extractive, 75 parts, and a red gum, 25 parts. It is used only as an astringent in medicine. Kino is often called a gum, but most improperly so.

KIP. A Malacca weight for tin, of 40 lbs. 11 oz. avoirdupois.—N. M. S.

KIPS. The tanners call the skins of young animals kips.

KIRSCHWASSER, is an alcohol-like liquor obtained by fermenting and distilling bruised cherries, called *Arachen* in German. The cherry usually employed in Switzerland and Germany is a kind of *myrica*, which on maturation becomes black, and has a kernel very large in proportion to its pulp. When ripe, the fruit, being some to feel by switching the trees, is gathered by children, thrown promiscuously, unripe, ripe, and

rotten, and to be, and crushed either by hand, or with a wooden beater. The mashed materials are set to ferment, and when the process is complete, the whole is transferred to a still, and the spirit is removed by passing the put over the common fire.

The fermented mash is usually made before it is put in the still, the capital of which is fitted on with a mixture of wood and dung. The liquor has a strong, for the most part, a rank smell, and is most injurious to health, but is from its own medicinal qualities, but from the presence of a derivative from the fermentation of the cherry-stone.

There is a superior kind of kreosote made in the Black Forest, prepared with fewer herbs, from a better spirit, properly fermented, bottled, and distilled.

KIRWANITE. A mineral found in basalt on the north-eastern coast of Ireland, consisting of a silicate of iron, alumina, and protoxide of iron.

KNIFE-CLEANING MACHINES. Mr. Kent's machine for this purpose consists of a box or frame, containing a couple of wooden drums, fixed near to each other upon a horizontal iron rod or spindle, which passes through the frame and is caused to rotate by means of a wheel-handle. Each drum is, for about three-fourths of the area of its lower face, covered with alternate rows of bristles and strips of leather, and the remaining fourth part is covered with bristles only. The bristles to be cleaned are introduced through the openings in the frame, between the rubbing surfaces of the drums, and rotary motion being given to the drums by a wheel-handle, the knives are rapidly cleaned and polished.

Mr. Mason's improved knife-cleaning machine is on the same plan as the above; but the rubbing surface of each drum is formed of strips of buff leather, with only a narrow circle of bristles around the edge of each surface, to clean the shoulders of the knives. Small brushes are fixed beneath the bottom of the case, through which the blades of the knives are inserted, to prevent the dust of dust from the apparatus.

Mr. Price has also devised a machine for cleaning knives, and another for cleaning forks. The knife-cleaner consists of a horizontal drum, covered with pieces of leather or buff, and fixed within a frame or circular frame, lined with leather or felt. The knives are introduced through openings in a movable circular plate, at the front of the outer casing, and enter between the surfaces of the two drums. The plate is fixed upon a horizontal axis, which extends through the frame, and is revolved at the back with a handle, by turning which the drum is caused to rotate and carry round the knives between the surfaces of the drums. The fork-cleaner consists of a box, with a long rectangular opening in the side, behind which two brushes are fixed, face to face. Between these brushes the prongs of the forks are introduced, and the handles are secured in a carrier, which is made to advance and recede alternately by means of a screw-drunk, and thereby thrust the prongs into and draw them out of contact with the brushes. The carrier consists of two metal plates, the lower one carrying a cushion of vulcanized indiarubber for the fork handles to rest upon, and the upper one lined with leather; they are joined together at one end, and are connected at the other, when the handles have been placed between them, by a thumb-screw.

KNOLLS. A kind of stone in Germany for lead ore separated from the smaller parts.

KNOPPERS are cankers produced by the puncture of an insect upon the flower-buds of several species of oak. They are compressed or flat, irregularly pointed, generally prickly and hard when ripe. They abound in Syria, Croatia, Servonia, and Nassau; those from the latter country being the best. They contain a great deal of tannin, are much employed in Austria for tanning, and in Germany for dyeing fawn, grey, and black. See GALLA.

KOLMISS is the name of a liquor which the Calmucks make by fermenting mare's milk, and from which they distil a favourite intoxicating spirit, called *sack* or *rudak*.

The milk is kept in bottles made of hides till it becomes sour, is shaken till it casts up its cream, and is then set aside in earthen vessels, in a warm place to ferment, no yeast being required, though sometimes a little old kolmiss is added. 21 pounds of milk put into the still afford 14 ounces of low wines, from which 6 ounces of pretty strong alcohol, of an unpleasant flavour, are obtained by rectification.

KOURIE WOOD. The wood of the New Zealand pine *Diospyros Australis*, one of the most magnificent of the gum-woods. It is also called *roudie* and *lawie* wood. It is much used for the masts of ships.

KRAMERIA. A shrub, which is a native of Peru, yielding the well-known rhizany root, often used as a diuretic.

KREOSOTE, or CHLOSOTE. One of the many singular bodies discovered by Reichenbach in wood-tar. It derives its name from *kreos* (from *kreos* and *osmē*), I preserve, in allusion to its remarkable antiseptic properties. A great deal of confusion exists in the published accounts of wood-kreosote, owing to the variable nature of the results obtained by the chemists who have examined it. This confusion is not found with that from coal, which undoubtedly contains two homologous bodies, C₁₀H₈O and C₁₁H₈O₂; the first being carbolic, and the second cresylic acid. The composition of carbolic acid has long been

LAC. (*Laque*, Fr.; *Lack*, *Lackforben*, Germ.) A resinous substance produced by the puncture of a peculiar female insect, called *Coccus lacca* or *ficus*, upon the branches of several plants, as the *Ficus religiosa*, the *Ficus Indica*, the *Rhusmannijuba*, the *Croton laciferum* or *hairy tree*, and the *Urtica frondosa* or the paper tree, which grow in Siam, Assam, Pegu, Bengal, and Malabar. The twig becomes thereby incrustated with a reddish mammillated resin, having a crystalline-looking fracture.

The female lac insect is of the size of a louse; red, round, flat, with 12 abdominal circles, a bifurcated tail, antennae, and 6 claws, half the length of the body. The male is twice the above size, and has 4 wings; there is one of them to 3000 females. In November or December the young brood makes its escape from the eggs, lying beneath the dead body of the mother; they crawl about a little way, and fasten themselves to the bark of the shrubs. About this period the branches often swarm to such a degree with this vermin, that they seem covered with a red dust; in this case, they are apt to dry up, by being exhausted of their juices. Many of these insects, however, become the prey of others, or are carried off by the feet of birds, in which they attach themselves, and are transplanted to other trees. They soon produce small nipple-like incrustations upon the twigs, their bodies being apparently glued, by means of a transparent liquor, which goes on increasing to the end of March, so as to form a cellular texture. At this time the animal resembles a small oval bag, without life, of the size of a chinkal. At the commencement, a beautiful red liquor only is jetted out, afterwards eggs make their appearance; and in October or November, when the red liquor gets exhausted, 50 or 60 young ones bore a hole through the back of their mother, and come forth. The empty cells remain upon the branches. These are composed of the milky juice of the plant, which serves as nutriment to the insects, and which is afterwards transformed or elaborated into the red colouring matter that is found mixed with the resin, but in greater quantity in the bodies of the insects, in their eggs, and still more copiously in the red liquor excreted for feeding the young. After the brood escapes, the cells contain much less colouring matter. On this account, the branches should be broken off before this happens, and dried in the sun. In the East Indies this operation is performed twice in the year; the first time in March, the second in October. The twigs encrusted with the radiated cellular substance constitute the *stick-lac* of commerce. It is of a red colour more or less deep, nearly transparent, and hard, with a brilliant conchoidal fracture. The stick-lac of Siam is the best; it often forms an incrustation fully one quarter of an inch thick all round the twig. The stick-lac of Assam ranks next; and, last, that of Bengal, in which the resinous coat is scanty, thin, and irregular. There are three kinds of lac in commerce: stick-lac, which is the substance in its natural state, seed-lac, and shell-lac. According to the analysis of Dr. John, stick-lac consists, in 100 parts, of

An odorous common resin	- 80.00	Fatty matter, like wax	- 3.00
A resin insoluble in ether	- 20.00	Skins of the insects, and colour-	
Colouring matter analogous to		ing matter	- 2.50
of that of cochineal	- 4.50	Salts	- 1.25
Bitter balsamic matter	- 3.00	Earths	- 0.75
Dark yellow extract	- 0.50	Loss	- 4.75
Acid of the stick-lac (laccic acid)	0.75		130.00

According to Franke, the constituents of stick-lac are, resin, 65.7; substance of the lac, 24.3; colouring matter, 0.6.

Seed-lac.—When the resinous concretion is taken off the twigs, coarsely pounded, and triturated with water in a mortar, the greater part of the colouring matter is dissolved, and the granular portion which remains being dried in the sun, constitutes *seed-lac*. It contains of course less colouring matter than the stick-lac, and is much less soluble. Mr. Hatchett's analysis of seed-lac was as follows:—

Resin	- 68	Foreign bodies	- 6.5
Colouring matter	- 10	Loss	- 6
Wax	- 6		
Glass	- 5.5		100

John found in 100 parts of it, resin, 86.7; wax, 1.7; matter of the lac, 16.7; bitter balsamic matter, 2.5; colouring matter, 3.9; dark yellow extract, 0.4; envelopes of insects, 2.1; laccic acid, 0.0; salts of potash and lime, 1.0; earths, 6.6; loss, 4.2.

Shell-lac.—In India the *seed-lac* is put into oblong bags of cotton cloth, which are held over a charcoal fire by a man at each end, and, as soon as it begins to melt, the bag is twisted so as to strain the liquefied resin through its substance, and, to make it drop upon smooth stems of the banyan tree (*Morus purpurea*). In this way, the resin spreads into thin plates, and constitutes the substance known in commerce by the name of *shell-lac*.

The Pegu stick-lac, being very dark coloured, furnishes a stick-lac of a corresponding deep hue, and therefore of inferior value. The pure red from shell-lac is brought from the Malabar Coast. It is much very little colouring matter. A stick-lac of an intermediate kind comes from the Mysore country, which yields a brilliant scarlet and a good shell-lac.

Shell-lac, by Mr. Hattett's analysis, consists of resin, 50; wax, 25; colouring matter, 25; wax, 4; gum, 2; loss, 1; in 100 parts.

The resin may be obtained pure by treating shell-lac with cold alcohol, and filtering the solution in order to separate a yellow very impure resinous matter. When the alcohol is again distilled off, a brown, translucent, hard, and brittle mass of resinous matter remains. It melts into a viscous mass when heated, and assumes an orange colour. A hydrous alcohol dissolves it in all proportions. According to John, it consists of two resins, one of which dissolves readily in alcohol, ether, the volatile and fat oils; while the other is little soluble in alcohol, and is insoluble in ether and the volatile oils. Unwin, however, has demonstrated that this resin is a single resin, and some other substances in shell-lac. Macleod therefore washes with ether, mastic, and acetic acids, but not in concentrated sulphuric acid. The resin of shell-lac has a great tendency to combine with alkaline bases, as well as metallic oxides, where it is derived of an alkaline base.

This substance, which is of a dark red colour, dries into a brilliant, transparent red-lac upon mats, which may be re-dissolved in both water and alcohol. By passing chlorine in contact through the shell-lac, and all the same manner, the lac-resin is precipitated in a colourless state. When this precipitate is washed and dried, it forms with alcohol an extremely pale-yellow varnish, especially with the addition of a little turpentine and mastic.

With the aid of heat, the shell-lac dissolves readily in a mixture of lye and

The substances which have been found in shell-lac are the following:

1. A resin, soluble in alcohol and ether;
2. A resin, soluble in alcohol, insoluble in ether;
3. A resinous body, little soluble in cold alcohol;
4. A crystallisable resin;
5. A resin, soluble in alcohol and ether, but insoluble in petroleum, and uncrystallisable.
6. The unsaponifiable fat of the coccos kernel, as well as olive and margarine seeds.
7. Wax.
8. The lac-resin of Dr. John.
9. An extractive colouring matter.

Shell-lac is largely used in the manufacture of sealing wax and varnishes, and for japanning.

LAC-DYE, LAC LAKE, or *cake-lac*, is the watery infusion of the ground stick-lac, evaporated to dryness, and formed into cakes about two inches square and half an inch thick. Dr. John found it to consist of colouring matter, 50; resin, 25, and solid matter, composed of alumina, plaster, chalk, and sand, 25.

Dr. Macleod, of Madras, states that he prepared a very superior lac-dye from stick-lac, by digesting it in the cold in a slightly alkaline decoction of the dried leaves of the *Memecylon tinctorium* (perhaps the *M. caput-meduse*, from which the natives of Malabar and Ceylon obtain a saffron yellow dye). This solution being used along with a mordant consisting of a saturated solution of tin in muriatic acid, was found to dye woollen cloth of a very brilliant scarlet hue.

The cakes of lac-dye imported from India, stamped with peculiar marks to designate their different manufacturers (the bear D^r, the second JMcR, the third CE), are now employed in England for dyeing scarlet cloth, and are found to yield an equally brilliant colour, and one less easily affected by perspiration than that produced by cochineal. When the lac-dye was first introduced, sulphuric acid was the solvent applied to the pulverised cakes, but as muriatic (hydrochloric) acid has been found to answer, it has to a great extent supplanted it. A good solvent (No. 1) for the dye-stuff may be prepared by dissolving 5 pounds of tin in 60 pounds of muriatic acid, of specific gravity 1.19. The proper mordant for the cloth is made by mixing 27 pounds of muriatic acid of sp. gr. 1.17, with 1½ pounds of nitric acid of 1.19; putting this mixture into a salt-glazed stone bottle, and adding to it in small lots at a time, grain by grain, till 4 pounds be dissolved. This solution (No. 2) may be used within twelve hours after it is made, provided it has become cold and clear. For dyeing, three quarters of a pint of the solvent No. 1 is to be poured upon each pound of the pulverised lac-dye, and allowed to digest upon it for six hours. The cloth being subjected to the dye bath, must be secured in the mill with fustic's earth. To dye 100 pounds of pelase cloth, a tin boiler of 300 gallon capacity should be filled nearly brimful with water, and a fire kindled under it. Whenever the temperature

ries to the Fabr., a handful of soap, and half a pint of the solution of tin (No. 2) are to be introduced. The flesh, which goes as it approaches extinction, must be skimmed off; and when the liquor has 1½ pounds of lac-dye, previously mixed with 7 parts of the solvent No. 1, and 2½ pounds of solution of tin No. 2, must be poured in. An instant afterwards, 1½ pounds of tartar, and 4 pounds of ground sumach, both tied up in a linen bag, are to be introduced in the boiling bath for five minutes. The fire being now withdrawn, 20 gallons of cold water, with 1½ pints of solution of tin being poured into the bath, the cloth is to be immersed in it, moved about rapidly during ten minutes; the fire is to be then re-kindled, and the cloth moved more slowly through the bath, which must be made to boil as quickly as possible, and maintained at that pitch for an hour. The cloth is to be next washed in the river; and lastly with water only, in the fulling mill. The above proportions of the ingredients produce a brilliant scarlet tint, with a slightly purple cast. If a more orange hue be wanted, white Florence argal may be used, instead of tartar, and some burnt sumach. Lac-dye may be substituted for cochineal in the same manner.

To determine the tinctorial power of lac-dye by experiment, with proved samples, a dye-bath is prepared as follows:—5 grains of argal, 20 grains of the seller's white cloth, 2 grains of lac-dye, 8 grains of chloride of tin, 1 quart of water. Heat the water to the boiling point in a tin or brass vessel; add thereto the argal, and then the piece of cloth or flannel. Weigh off 5 grains of the lac-dye and pulverise it in a Wedgwood mortar, with the 8 grains by measure of chloride of tin, and pour the whole into the hot liquor containing the cloth, taking care to stir the mortar with a stick in the hot liquor; keep the whole boiling for about half an hour stirring the cloth or flannel about with a glass rod; then withdraw the cloth, wash and dry it for comparison. — *Norman.*

In the former edition was a table of the imports and exports of lac-dye and lac-like, which show that in 1852 only 253 lbs. were imported, which rose, however, in 1857, to 1,011,674 lbs.; the imports, &c., for the last three years being—

LACCIC ACID crystalline, has a wine-yellow colour, a sour taste, is soluble in water, alcohol, and ether. It was extracted from black-lac by Mr. John.

LACCINE is the portion of shell-lac which is soluble in alcohol. It is brown, brittle, translucent, consisting of aggregated pellucles, more like a resin than anything else. It is insoluble in ether and oils. It has not been applied in any use.

LACE BARK. The reticulated bark of the *Lagetta lanceolata*. This splits into fibres, which resemble lace.

LACE MANUFACTURE. The pillow-made, or bone-lace, which formerly gave occupation to multitudes of women in their own houses, has, in the progress of mechanical invention, been nearly superseded by the bobbin-net lace, manufactured at first by hand-machines, but recently by the power of water or steam. Bobbin-net may be said to surpass every other branch of human industry in the complex ingenuity of its machinery; one of Fisher's spinning frames being as much beyond the most curious chronometer in multiplicity of mechanical device, as that is beyond a common roasting-jack. — *Ure.*

The threads in bobbin-net lace form, by their intertwining and decussation, regular hexagonal holes or meshes, of which the two opposite sides, the upper and under, are directed along the breadth of the piece, or at right angles to the selvage or border. Fig. 1034 shows how, by the crossing and twisting of the threads, the regular six-sided mesh is produced, and that the texture results from the union of three separate sets of threads, of which one set proceeds downwards in serpentine lines, a second set proceeds from the left to the right, and a third from the right to the left, both in slanting

directions. These threads twist themselves round the vertical ones, and thus form a net, the warp threads, in a parallel manner. This may be easily understood by examining the preceding plate. In comparing this net with a common web, the perpendicular threads in the figure which are parallel to the border, may be regarded as the warp, and the two sets of slanting threads as the weft.

1054

1055

The warp threads are extended up and down in the longitudinal direction of the piece between a top and bottom horizontal roller or beam, of which one is raised the warp beam, and the other the lace beam, because the warp and the lace beam are wound upon them respectively. These slanting warp threads receive their extension from the tension of the weft threads twisted obliquely round them alternately in the right and the left hand. Were the warp threads not tightly drawn, that they become flexible, like the strings, then the lace would assume the appearance shown in fig. 1053, and although this condition does not really exist, it may serve to illustrate the structure of the web. The warp threads start in the position *a a*, *a' a'*, and *a'' a''*; the middle of the weft proceeds in the direction *b c*, *b' b'*, and *b'' b''*, and the second crosses the first by running in the direction *c e*, *c' e'*, towards the opposite side of the fabric. If we pursue the path of a weft thread, we find it goes on till it reaches the outermost or last warp thread, which it twice encircles, as with the others, but twice; and then returning towards the other border, passes in a reverse direction. It is from this double twist, and by the return of the weft threads, that the selvedge is made.

The ordinary material of bobbin-net is two cotton yarns, of from No. 16 to No. 20, twisted into one thread; but sometimes strongly twisted single yarn has been used. The beauty of the fabric depends upon the quality of the material, as well as the regularity and smallness of the meshes. The number of warp threads is a yard in breadth is from 600 to 900, which is equivalent to from 20 to 30 in an inch. The size of the holes cannot be exactly inferred from that circumference, as it depends partly upon the oblique traction of the threads. The breadth of the pieces of bobbin-net varies from edges of a quarter of an inch to webs 12 or even 20 quarters, that is, 3 yards wide.

Bobbin-net lace is manufactured by means of very costly and complicated machines, called frames. The limits of this Dictionary will admit of no explanation of so more than the general principle of the manufacture. The threads for winding and twisting round the warp, being previously gassed, that is, freed from loose fibres by steeping with gas, are wound round small pulleys, called bobbins, which are, with the view, deeply grooved in their periphery. Figs. 1056, 1057, exhibit the bobbin alone, and with its carriage.

In the section of the bobbin *a*, fig. 1056, the deep groove is shown in which the thread is wound. The bobbin consists of two thin discs of brass, cut out in a lamp-press, in the middle of each of which there is a hollow space *c*. These discs are pressed together leaving an interval between their edge all round, in which the thread is coiled. The round hole in the centre, with the little notch at top, serves for putting them upon a feathered rod, in order to be filled with thread by the rotation of that rod in a species of reel, called the bobbin-filling machine. Each of these bobbins (about double the size of the figure) is inserted into the vacant space *a* of the carriage, fig. 1057. This is a small iron frame (also double the size of the figure), which, at *c c*, embraces the grooved border of the bobbin, and by the pressure of the spring at *f*, prevents it from falling out. This spring serves likewise to apply sufficient friction to the bobbin, so as to prevent it from giving off its thread at *g* by its rotation.

unless a certain small force of traction be employed upon the thread. The curvilinear groove A A, sunk in each face or side of the carriage, has the depth shown in the sec-

tion at A. The groove corresponds to the interval between the teeth of the comb, or bars of the belt, in which each carriage is placed, and has its movement. A portion of that bolt or comb is shown at a, *fig.* 1036 in plan, and one bar of a circular bolt machine at b, in section. If we suppose two such combs or bolts placed with the ends of the teeth opposite each other, but a little apart, to let the warp threads be stretched, in one vertical plane, between their ends or tips, we shall have an idea of the skeleton of a bolt-net machine. On of these two combs, in the double bolt machine, has an occasional lateral movement called *shooting*, equal to the interval of one tooth or bolt, by which, after it has received the bobbins, with their carriages, into its teeth, it can shift that interval to the one side, and thereby get into a position to return the bobbins, with their carriages, into the next series of intervals or gates in the other bolt. By this means the whole series of carriages receives successive side steps to the right in one bolt, and to the left in the other, so as to perform a species of counter march, in the course of which they are made to cross and twist round about the vertical warp threads, and thus to form the meshes of the net.

The number of movements required to form a row of meshes in the double tier machine, that is, in a frame with 2 combs or bars, and 2 rows of bobbins, is six, that is, the whole of the carriages (with their bobbins) pass from one bar or comb to the other six times, during which passages the different divisions of bobbin and warp threads change their relative positions 12 times.

The interchange or traversing of the carriages with their bobbins, which is the most difficult thing to explain, but at the same time the most essential principle of the lace-machine, may be tolerably well understood by a careful study of *fig.* 1038, in which the simple line | represents the bolts or teeth, the sign ϕ the back line of carriages, and the sign ϕ the front line of carriages. It is the front comb or bolt bar, and 1 the back bolt

bar. The former remains always fixed or stationary, to receive the carriages as they may be presented to it by the shooting of the latter. There must be always one odd carriage at the end; the rest being in pairs.

small trouble and expense a very large quantity of product. In fact, he has prepared with facility upwards of three parts of lactic acid from lactate of lime obtained in this manner. Dissolve 6 lbs. of lump sugar, and half an ounce of tartaric acid in two gallons and a half of boiling water. Leave for a day or two, and then add two ounces of rotten cheese, and a gallon of skimmed milk stirred up with three pounds of well washed prepared chalk. The temperature should not fall below 66° F., nor rise above 90°. The water lost by evaporation must be made up by adding a little every few days. After a time, varying from ten days to a month, according to the temperature and other circumstances, the whole becomes a magma of acetate of lime. Two gallons of boiling water must then be added, and half an ounce of quicklime and the whole, after being boiled for half an hour, is to be filtered through a linen or flannel bag. The filter should be to be evaporated until it begins to get somewhat syrupy, the fluid in the stove being put aside to allow the salt to crystallize. The crystals, after being slightly washed with cold water, are to be recrystallized two or three times. To obtain lactic acid from the lactate of lime, it is necessary, in the first place, to convert the latter salt into that of zinc. For this purpose a crude lactic acid is first obtained thus: to every two pounds three ounces of lactate of lime dissolved in twice its weight of boiling water, seven ounces of oil of vitriol previously diluted with twice its volume of water are to be added. The boiling fluid is to be strained through a linen bag to remove the precipitate of gypsum, and the filtered liquid is to be boiled for 15 minutes with 1½ ounces of carbonate of zinc. The boiling must not be continued longer, or a violent effervescence will be produced. The liquid, which is to be filtered through a wet deposit on cooling the lactate of zinc in colourless crystals, which are to be washed with a little cold water, and after being drained are to be dried by exposure to the air in frames covered with filtering paper. The mother liquid will yield a fresh quantity of lactate if it be boiled with the salt remaining on the filter and evaporated.

From the lactate of zinc the acid is to be separated by passing sulphuretted hydrogen through the solution of the salt in eight times its weight of boiling water. The gas is to be expelled by heat, and the fluid on evaporation yields pure syrupy lactic acid.

Lactic acid is a colourless syrupy liquid of a powerful pure acid taste. Its specific gravity is 1.115. It is bibasic, consequently the general formula for the lactates is $C^3H^3O^4, 2MO, M$ representing any metal.

The most important salts of lactic acid are those of zinc and lime. The former salt is that generally formed in examining animal or vegetable fluids with a view to the isolation of the acid. It is found with two different quantities of water according to the circumstances under which it is prepared, and it is worthy of remark that the amount of water of crystallisation remarkably affects the solubility of the salt in water and alcohol.

Lactic acid is produced from alanine by the action of nitrous acid according to the following equation. —

Anhydrous lactic acid, $C^3H^5O^4$, is produced by the action of heat on the syrupy acid. Lactic acid is considered by chemists to be constructed on the type of four atoms of water in which two atoms of hydrogen are replaced by the radical lactyl, thus: — $\left. \begin{matrix} C^3H^5O^4 \\ H^2 \end{matrix} \right\} O^2$.

The other two atoms of hydrogen are consequently basic. It has been said that lactic acid may, by fermentation, be converted into butyric acid; the following equation represents the metamorphosis.

All the butyric acid employed for the preparation of butyric ether, or pine-apple essence, is now prepared by the fermentation of lactate of lime, — C. G. W.

LACQUER, is a varnish, consisting chiefly of a solution of pale shell-lac in alcohol, tinged with saffron, annatto, or other colouring matters. See VANSTEN.

LACTOMETER is the name of an instrument for estimating the quality of milk, called also a Galactometer. The most convenient form of apparatus would be a series of glass tubes each about 1 inch in diameter, and 12 inches long, graduated through a space of 10 inches, to tenths of an inch, having a stopcock at the bottom, and suspended upright in a frame. The average milk of the cow being poured in to the height of 10 inches, as soon as the cream has all separated at top, the thickness of its

Only may be measured by the scale; and then the slowness may be run off by a
small horizontal glass, in order to determine its quantity by the velocity of descent in a small
manometer, and deliver with water.

Brazil wood is a red dye. The wood is used as a preservative for lumber for 15 years, and then also as a substitute of the long used, but expensive, colored and stained pine wood in as long as it remains a preservative. This is separated by a filter, the powder is washed, and being sold for a little gum water, and is in cash. Because the Brazil wood is a dye, it is very good of white. An excess of powder produces a lake of a white color, and is used of tarter gives a brown line.

Ma... .. is the proportion of taken

The title of the paper is *unintentional* —

1866. 1 lb. of gum mastic, 4 lb. of water, and after a maceration of 10 days, strain and squeeze the grounds in a press. Repeat the same process. Ac. 1 lb. upon the same part of mastic. It will be a fine yellow color. It must then be mixed with five or six pounds of water and half a pound of hydrated alum, and heated upon a water-bath for 3 or 4 hours, with the addition of water, as it evaporates; after which the whole must be thrown on a filter. The liquor which passes through is then to be filtered through paper, and precipitated by carbonate of potash. If potash be added in three successive doses, three different colors will be obtained of diminishing beauty. The precipitates must be washed until the water comes off colourless, then with gum water made into cakes.

Yellow Lake: are made with decoctions of Persian or French berries, to which some potash or soda is added: into the mixture a solution of alum is to be poured so long as any precipitate falls. Quercitron will yield a yellow lake, provided the decoction is purified by either butter-milk or glue. Annott lake is formed by dissolving this substance in a weak alkaline lye, and adding a solution of alum to the solution.

Lakes of other colours can be prepared in a similar manner; but true lakes of other colours are not usually manufactured.

LAMINABLE is said of a metal which may be extended by passing between steel or hardened (chilled) cast-iron rollers.

In the manufacture of rail and bar iron, laminated iron is rolled together at a welding heat, until the required bar or rail is formed (see Rattle). This is, even under the best possible circumstances, a defective manufacture. The union of the bars is never absolutely complete, and the result of the long-continued action of traffic of carriages upon all rails is the development of the laminated plane, which frequently peels off, layer after layer, to the destruction of the rail, and to the great danger of the traveller. Railway iron should be rolled into form from perfectly homogeneous masses of metal. The lamination of iron rails has been laid hold of by those who advance the hypothesis that the slate rocks owe their lamination to mechanical pressure, whereas it is evident that the result of an imperfect manufacture. See RATTLE MILE.

LAMUM ALBUM or the dead nettle, is said by Leonhart to afford in its leaves a greenish-yellow dye. The *L. purpureum* dyes a reddish grey with salt of tin, and a greenish blue with iron liquor.

LAMP-BLACK. Every person knows that when the combustion of oil in a lamp is imperfect it pours forth a volume of dense black soot. According to the quantity

of carbon is used in the material employed, so is the illuminating power of the flame produced by combustion. If, therefore, we have a very brilliant flame, and we subject it to any conditions which shall impede the progress of the combination of the carbon with the oxygen of the air, the result is at once the formation of solid carbon, or lamp-black. This is exhibited in a remarkable and often an annoying manner by the lamp-lamp. If oil of turpentine, resin, pitch, or fat oil, be burnt in lamps under a hood, with either a rapid draught or an insufficient supply of air, the lamp-black collects on the hood, and is constantly removed. Sometimes a metallic roller, generally of tin, is made to revolve in the flame, and rub against a brush. By the cooling influence of the metal, the base of the flame is diminished, the combustion retarded, and the carbon deposited, and in the revolution of the cylinder swept off. Lamp-black burning forms a very beautiful black, which is sometimes used as a pigment.

The common varieties of lamp-black are made from all sorts of refuse and noxious matters, and from the rejected fragments of paper, &c. In Germany, a large fire is constructed in connection with the furnace in which the refuse substances are burnt, and this fire communicates with a hood, composed of a loose wooden cloth, held up by a rope passing over a pulley. Upon this the soot collects, and is from time to time shaken down. In the best candle-manufactories about 3 cwt. of lamp-black is consumed in each hour in about twelve hours. In England, lamp-black is sometimes prepared from the refuse of the glass, or it is obtained in connection with coke ovens. The lamp-black, however, obtained from the combustion of coal or woody matter is never pure. See BLACK, LAMP, IVORY PLAIN.

LAMP, DAY. See SAFETY LAMP.

LAMPS. Under ILLUMINATION, will be found some account of several kinds of lamps, with especial reference to the quantity of light produced by them.

Lamps are very varied in form, and equally varied in the principles involved. A brief description, however, of a few of the modern varieties must suffice.

The *moderator lamp*.—The spiral spring has recently been introduced into the *moderator lamp*, for the purpose of forcing the oil up the wick of the lamp. This will be understood by the following description and drawings.—

1060

The distinguishing character of the *moderator lamp* is the direct transmission of the power, in the reservoir of oil, to the resistance offered by the weight of the column of oil, as it rises to the cotton;—and secondly, the introduction of a rectangular regulator, which equilibrates constantly by the resistance of the oil and the force applied to raise it. In the reservoir (fig. 1060), is a spiral spring which presses on the disc or piston, fig. 1061, which is furnished with a valve opening downwards. This spring is attached to a tooth rack, worked by a piston wheel, by the action of which it is wound up. The mechanical force of the spring is equal to from 15 to 20 pounds; and so this force is exerted upon the disc, forcing on the oil, this is forced up through the tube, and it overflows to the argand burner, thoroughly saturating the cotton, and supplying a constant stream of oil. This oil falls back into the reservoir, and is, of course, above the disc. When the spring has run down, it is again wound up, and then the valve opening downward allows the oil to flow back beneath the disc, to be again forced up through the tube. As the pressure employed is so great, the oil would, but for the "moderator," flow over with too much rapidity. The *moderator*, or regulator, is a tapering rod of iron-wire, which is placed in the ascending tube; and, as the pressure increases it is forced more into it, and checks the flow of oil; whereas as it diminishes it falls, and being tapering, allows more oil to rise. Several ingenious adjustments are introduced into these lamps, as manufactured by the Messrs. Tyler of Warwick Lane, with which we need not at present deal. The cylinders containing the oil are covered with enameled metal or sometimes of porcelain. Two drawings of these are shown (fig. 1062 and fig. 1063). These lamps admit evidently of yet more elegant forms than have been given them. The urn-shaped, from the antique, in very pure taste, is the last introduction of the house above named.

1061

It would be tedious to enumerate the various modifications of form and action to which the oil lamp has been subject, previous to its arrival at what may be deemed its perfect construction by Argand. The discovery of the mode of applying a new principle

the upper rim, and the margin, there is a small projecting pin *e*, which, when the whole apparatus is combined, fits into the cavity of the lower *l*. To prepare the lamp for use, the tube *u* is pushed between *A* and *a* as just described, the ring *r*, with its convex surface, is next inserted, the pin *e* of the middle fitting fits the spiral groove, and that of the outside moving the rest of the tube *u*, which, on being turned about, causes the lower *v* to slide along the curved lower tube, until the water only just rises above the lower *e* above of the tube, in the interval between which it lies in the oil. In this stage, the funnel *l* is placed in the neck in the collar at *e*, falling upon the pin over the top of it, the lower *f*, *f*, passing over the tube *A*, at once presents a convenient support for the glass chimney, and a finger-ring for raising the work. The central tube is open throughout, and, when unlighted, at its lower end, with the brass rim *A*, is closed as performed at top, to admit the air which, by circulating through the above tube, and the burning flame which surrounds it, causes the lamp to burn with that peculiar softness and brilliancy which distinguishes the Argand combustion. The last-mentioned receptacle *h* is a cap for any small quantity of oil which may pass over the lower tube during the combustion of the work. *z* is the brass peg, which fits into the upper part of the point, in the table lamp.

In addition to the various variety of small portable lamps, the production of which it would be tedious to particularise, and the merit of which, as compared with those of the Argand principle, remains, in the great part, in their cheapness, the more important articles, and those generally in demand, may be distinguished as fixed or bracket lamps, suspended or chandelier lamps, and table or French lamps—all these having, however, as the principle above described. The former sort were, previous to the introduction of gas, very common in shops. The given *A* (Fig. 1444), which is sometimes made plain and

is sometimes enclosed, as in the cut, set us off, when the oil is raised in at an opening in the lower part, which is afterwards closed by means of a slide attached to the stem, *n*, and the globe, thus replenished, is inverted and screwed into the part, *c*. When the lamp is used, the stem *n* is raised a little, and the oil is suffered to flow through the intermediate tube into the cavity *n*, only at the rate at which it is consumed by the burning of the wick. The peculiar form of the glass chimney *a* is admirably calculated to assist in the more complete combustion of the matter drawn up to the wick when impure oil is used, a deodorisation originally in part effected by placing over the central tube, and in the midst of the flame, a circular metal plate, by means of which the ascending column of air was turned out of its perpendicular course, and thrown immediately into that part of the flame where the smoke is formed, and which by this ingenious contrivance is effectually consumed; this application, however, is not necessary, nor the form of such moment, when purified sperm oil is used. These lamps being usually made to move on a pivot at *e*, attached to the wall or other support, are very convenient in many situations, as being easily advanced over a desk or counter, and afterwards turned aside, when not in use.

The chemical lamp has no possibility of improvement to be described.

The use of spirit lamps is limited, and we have the alcoholic and naphthalene lamps of the same kind. The alcoholic lamp, however (the latter shows the possibility of the naphthalene lamp where the reservoir of spirit is impregnated with oil) is far below the former, to which it is equalled by simplicity of construction, through the tubes of the same work. Lamps to burn naphthalene (Naphthalene, A.) are constructed on the same principle.

One of the best oil lamps, is that known as Cam's lamp.

In this lamp the oil is raised through some by clock work, as is commonly the case, at the bottom of the burning work, thus keeping it thoroughly agitated, while the excess of the oil drops back into the common reservoir. I have possessed the best of years an excellent lamp of this description, which performed most admirably; but it can hardly be trusted in the hands of a servant, and when a gets at all damaged it must be sent to the chemist to be repaired. The light of this lamp when furnished with an appropriate tall glass chimney, is very brilliant, though not perfectly uniform, since it fluctuates a little, but always perceptibly to a sensitive observer, with the alternating action of the pump-work, becoming almost a very successive jet of oil, and lighter just before its return. The flame, however, always thickens to a certain extent, owing to the powerful draught, and it is a good example of the shoulder of the chimney. The mechanical lamp is, however, remarkable for its economy in burn, and may with advantage be used with increasing splendour for 2 or 3 hours; the variety of the combustion increasing continually with the increased temperature and fluency of the oil, which by its constant circulation through the burning work, is eventually very warm. In the comparative experiments made upon different lights by the Philosophical Society, the mechanical lamp is generally taken as the standard. I do not think it equal to the phosphoric, but it may be made to emit very different quantities of light, according to difference in the nature and supply of the oil, as well as variations in the form and position of the chimney. Hence, such lamps as are rare in this country to be selected as standards of illumination.

The following experiments by Dr. Ure, are well worth preserving.

The great variety in the quality of lamps in the vicinity, and consequent irregular supply of oil, to the water, as shown nearly as perfect with lamps of the common construction during the winter months. The relative viscosity or relative fluency of different liquids at the same temperature, and of the same liquid at different temperatures, has not, I believe, been hitherto made the subject of accurate researches. I was, therefore, induced to make the following experiments with this view.

Into a brass chemical cup of platinum, resting on the ring of a chemical stand, I introduced 2000 grain-measures of the liquid whose viscosity was to be measured, and ran it off through a glass siphon, of an inch in the bore, having the outer leg 4 inches, and the inner leg 3 inches long. The time of efflux became the measure of the viscosity; and of two liquids, if the specific gravity and consequent pressure upon the siphon were the same, that time would indicate exactly the relative viscosity of the two liquids. Thus, oil of turpentine and sperm oil have each very nearly the same density; the former being, as sold in the shops, = 0.876, and the latter from 0.876 to 0.880, when pure and genuine. Now I found that 2000 grain-measures of oil of turpentine ran off through the small siphon in 93 seconds, while that quantity of sperm oil took 97 seconds, being in the ratio of 1 to 28; so that the fluency of oil of turpentine is 28 times greater than that of sperm oil. Pyroxene spirit, commonly called naphtha and alcohol, each of specific gravity = 0.82, were found to run off respectively in 84 and 120 seconds, showing that the former was 30 per cent. more fluent than the latter. Sperm oil, when heated to 100° Fahr., runs off in 90 seconds, or one-ninth of the time it took when at the temperature of 60°. Southern whale oil, having a greater density than the sperm oil, would flow off faster were it not more viscid.

2000 grain measures of water at 60° run off through the said siphon in 73 seconds, but when heated to 180° they run off in 61.

Concentrated sulphuric acid, though possessing the great density of 1.840, yet flows off very slowly at 60°, on account of its viscosity; whence its name of oil of vitriol. 2000 grain-measures of it took 660 seconds to discharge.

LAMPIC ACID. Syn. Aldehydic acid; Acetylous acid. (*Ac. Lampicæ*, Fr.) If a little ether be placed at the bottom of a glass, and some spongy platinum attached to a wire of the same metal be ignited and suspended about an inch from the fluid, it will glow and continue to do so for a long time. On the other hand, if a spiral of platinum wire be placed over the vessel of a spirit lamp, and the latter be first ignited and then blown out, the wire will continue at a red heat until all the spirit is consumed. Numerous sequiades, when placed warm on wire gauze over capsules containing

alcohol, will flow in the same manner. Under all these circumstances, a powerful colour resembling aldehyde is evolved, which severely affects the eyes. If this experiment be made in such a manner that the volatile product may be condensed, it will be found to be strongly acid. It is powerfully reducing in its tendency, and if treated with the oxides of silver or gold, converts them into the metallic state, and the liquid is found to contain acetic acid and traces of aldehyde. If, however, the acid liquid be only very greatly warmed with a little of silver, a portion of the latter is dissolved; but when baryta is added to precipitate the silver as oxide, and the fluid is warmed, the metallic baryta of the oxide comes down, and the fluid when tested for the nature of the acid is found to react in reacting but acetate of baryta. These phenomena are explained by some chemists by supposing the fluid to contain an acid which they, following the late Professor Daniell, call the lampic acid, and supposed to contain $C^{II}PO^2$. When lampic acid is treated first with oxide of silver and then with baryta water and heated, they consider that the oxygen of the oxide of silver is transferred to the lampic acid, converting it into acetic acid, which combines with the baryta, while the metallic silver is precipitated. The following equation expresses the reaction supposed to take place:—

Lampic acid.

Acetate of baryta.

The conversion of the lampic into acetic acid is therefore attributed to the oxidising tendency of the oxide of silver. Those who regard the decomposition from the above point of view, consider lampic acid to be acetylous acid, that is to say, to bear the same relation to acetylous acid (acetic acid) that acetylarous acid does to acylous acid.

The above explanation, although simple, does not really render a satisfactory account of the reaction which bears upon the subject. Aldehyde, when treated with oxide of silver does, it is true, become converted into the same, or apparently the same, substance as lampic acid, but the probability is in favour of Gerhardt's supposition, that the lampates are in fact aldehydyle, in which an equivalent of hydrogen is replaced by a metal. That the aldehydes are capable of uniting with metals with elimination of hydrogen has been, on more than one occasion, proved by experiment. There is great difficulty in preparing the sodium aldehyde of the same series, but the author of this article has found that if caustic aldehyde from oil of rose be treated with sodium, a definite compound is formed, having the formula $\frac{C^{II}H^2(PO^2)}{Na}$.

If, therefore, we admit aldehyde to be formed on the hydrogen type, that is to say, two atoms of hydrogen in which one is replaced by the oxidised radical acetyl, we shall have for aldehyde:— $\frac{C^{II}H^2(PO^2)}{H}$; and for the lampates, acetylous, or aldehydylates:— $\frac{C^{II}PO^2}{M}$.

M. Gerhardt, who views the lampates in the above light, regards aldehyde as the true acetylous acid. See ACETYL.—C. G. W.

LANCE WOOD (*Coccoloba lanceolata* or *Gousteria vrayana*). This wood is imported from Jamaica and Cuba in long poles from 3 to 6 inches diameter. Lance wood is paler in colour than box; it is selected for elastic works, as gig-shafts, archery bows, springs, &c. These are bent into the required form by boiling or steaming. Surveyor's rods, ordinary rules and billiard cues are made of lance wood.

LANDER. In mining, the man who attends at the mouth of the shaft to receive the "hibble of ore" as it reaches the surface.

LAPIDARY, *Art of*. The art of the lapidary, or that of cutting, polishing, and engraving gems, was known to the ancients, many of whom have left mineral specimens of their skill. The Greeks were passionate lovers of rings and engraved stones; and the most personifications among the higher classes of the Cyrenians are said to have worn rings of the value of ten minæ (about 30*l.* of our money). By far the greater part of the antique gems that have reached modern times may be considered as so many models for forming the taste of the student of the fine arts, and for inspiring his mind with correct ideas of what is truly beautiful. With the cutting of the diamond, however, the ancients were unacquainted, and hence they wore it in its natural state. Even in the middle ages, this art was still unknown; for the four large diamonds which enrich the clasp of the imperial mantle of Charlemagne, as now preserved in Paris, are uncut, octahedral crystals. But the art of working diamonds was probably known in Hindostan and China in very remote periods. After Louis de Berghem's discovery, in 1476, of polishing two diamonds by their mutual attrition, all the finest diamonds were sent to Holland to be cut and polished by the Dutch artists, who long retained a superiority, now no longer admitted by the lapidaries of London and Paris. See DIAMOND.

The operation of gem cutting is performed by two wheels, 1, by revolving it by turning it round with a fine wire, wound with diamond powder, and fixed to the neck of a handle. I mention to the only process which is not carried out with diamond powder, worked with other materials, as the plate of very soft lead.

Orbital rubber supplies, and lapidary are cut with diamond powder worked with lead, on a rough wheel. The stone they support are afterwards polished by another softer wheel, with cloth, composed with water.

Finally, by another smooth, fine, garnet, agate, and other softer stones are cut on a low wheel, with emery and water, and are polished on a soft wheel with pitch and water, or, still better, on a fine wheel, with pieces of the said stone.

The more highly polished stones, and even the garnet, are cut on a soft wheel of hard wood, with emery and water, and are polished with crystal and water on another wheel of hard wood.

Now the lapidary says it is always the same tools, whatever be the stone which he cuts or polishes, and says the wheel stone alone vary, so that the processes be the same; but, we shall show the first of all, the operation, and then the manipulations for diamond cutting, which are appropriate to every species of stone.

The lapidary's mill, or wheel, is shown in perspective in fig. 1067. It consists of a strong frame made of oak, composed, with three feet square joints, fixed together with strong bolts and screw down. The frame is a parallelogram of four feet by three feet, by four feet high, and about 2 feet wide. These dimensions are large enough to contain two cutting wheels, the diameter of each wheel, as represented in the figure.

Between the two wheels there is, we perceive in the figure, a third beam, to *a, b, c, d*. The two wheels have each, on a part of the frame work, and serve to hold it. The two wheels are 1 and 2, carry each in the middle of their length, a piece of wood as thick as themselves, but only 4 inches long.

Between the two wheels there is, we perceive in the figure, a third beam, to *a, b, c, d*. The two wheels have each, on a part of the frame work, and serve to hold it. The two wheels are 1 and 2, carry each in the middle of their length, a piece of wood as thick as themselves, but only 4 inches long.

(see fig. 1067). I intend to say by means of a screw and nut, with that screw bar as well as with the one placed against the other, the wheel stone. These two pieces are called *summers* (lines), the one placed at *b* is the upper; the one at *c* is the lower.

In fig. 1068 this face is shown better, in order to explain how the wheel is placed and supported. The same letters point out the same things, both in the perspective and the following figure.

In each of these *summers* a square hole is cut out, exactly opposite to the other, which are adjusted by friction a square piece of oak, as in fig. 1068, whose extremities are perforated with a round hole, which receives the two ends of the arbor *n* of the wheel 1, and forms its socket. The square bar is adjusted at a convenient height by a double written wedge, *b, b*.

The cross bar in the middle *x*, supports the table *e*, a strong plank of oak. It is perforated with two large holes, whose centres coincide with the centres of the round holes hollowed out at the end of the square piece. These holes of about 6 inch diameter each, are intended to let the arbor pass freely through near to the opposite wheel. (See also of these holes at *i*, in fig. 1069 below.)

Each wheel is composed of an iron arbor *n*, in the middle of a grinding wheel 1, which differs in substance according to circumstances, as a ready stated, and of the pulley *s*, furnished with several grooves (see fig. 1067), which has a square fit upon the arbor. The arbor carries a nut *d*, which are 4 iron pegs of pine that enter into the wheel to fasten it.

The wheel plate, of which the ground piece is cut out at *n*, is hollowed out towards its centre to half its thickness when it is in its position on the arbor, so intended to diminish the weight of the wheel. In fig. 1069 the wheel-plate is represented in section, the construction of the wheel parts may be seen.

A board *y* (see fig. 1067 and fig. 1073), about 7 inches high, is fixed to the

1069, a washer or ferrule of wrought iron is put over it, and secured in its place by a double wedge. In fig. 1069 the wheel-plate is represented in section, the construction of the wheel parts may be seen.

A board *y* (see fig. 1067 and fig. 1073), about 7 inches high, is fixed to the

part of the frame opposite to the side at which the lapidary works, and it prevents the cutters made use of in the cutting and grinding from being thrown out of position by the centrifugal force of the wheel.

Behind this apparatus is mounted for each grinding-plate, a large wheel *L* (see fig. 1077), similar to a cutter's, but placed horizontally. This wheel is grooved round its circumference to receive an endless cord or band, which passes round one of the grooves of the pulley *J*, fixed below the wheel-plate. Hence, on turning the fly-wheel *L*, the plate revolves with a velocity relative to the velocity communicated to the wheel *L*, and to the difference of diameter of the wheel *L* and the pulley *J*. Each wheel *L*, is mounted on an iron arbor, with a crank (see *fig. 1071*).

The lower pivot of that arbor *A* is conical, and turns in a socket fixed in the floor. The great wheel *L* runs on the collar *i*, furnished with its 4 iron pins, for securing the connection. Above the wheel an iron washer is laid, and the whole is fixed by a double wedge, which enters into the mortise *l*, *fig. 1071*.

Fig. 1072 exhibits a general plan view of all this assemblage of parts, to express the structure of the machine. Everything that stands above the upper counter has been expressed in this representation. Here we see the table *c c*; the upper counter *m*; the wheel-plate *l*, the other having been removed to show that the endless cord does not cross; the two large wheels *L L*, present in each machine; the crank bar *x*, seen separately in *fig. 1073*, which serves for turning the wheel *L*.

1072

This bar is formed of 3 iron plates *a*, *a* 1 *p*, *q* 1 and *q*, *r* (*fig. 1073*). The first is bent round at the point *a* to embrace the stud *s*; the second *p q* is of the same breadth and thickness as the first; and the third, *r*, is adjusted to the latter with a hinge joint, at the point *q*, where they are both turned into a circular form, to embrace the crank *x*. When all three pieces are connected, they are fixed at the proper lengths by the bolts or square rings *t t*, which embrace these pieces, as is shown in *fig. 1072*.

The stud *s*, seen in *fig. 1073*, is fixed to the point *r*, by a wedge-key upon the arm *p*, represented separately, and in perspective, in *fig. 1074*. The latter serving

1073

1074

the two upright pegs or handles *s s* 1 by the alternate forward and backward motion of his arm, he communicates the same motion to the crank rod, which transmits it to the crank of the arbor *x*, and impresses on that arbor, and the wheel which it bears, a rotary movement.

Fig. 1075 shows piece-meal and in perspective a part of the lapidary's wheel-mill. There we see the table *c c*, the grind plate *l*, whose axis is kept in a vertical position by the two square plugs *a a*, fixed into the two counters by the wedges *b b*. On the two sides of the wheel-plate, we perceive an important instrument called a *chal*, which

device to hold the stone during the cutting and polishing. That instrument has received lately important modifications, to be hereafter seen. The lapidary holds this instrument in his hand, so that it may strike the piece *a*, fixed on the table, and he should be assisted by the velocity of the revolving wheel-plate. He works it sometimes with water, &c., to make it take better hold of the grinding plane.

The 1776 shows an improvement made by one of the most expert lapidaries of Geneva, whereby he cuts and polishes the facet with a circular velocity, converting

it into a true oval. Each of the two jaws has a large rounded cavity, from which is drawn a brass ball, which carries on its lower part a table *e*, to whose extremity is fixed a diamond *f*, improved with several fine-pointed corners, divided into equal parts, like the pointed-wheel cutting engine-plate, according to the number of facets to be placed in each circular facet. The table moves with moderate friction on the handle of the round rod, which is fixed at the proper point by a thumb screw, and shown in the figure, being controlled by the vertical link *d*, that is to be described.

A guide or link *g*, fixed with a square fit on the end of the round rod, marks by its point the divisions on the dial plate *f*. On the side *b*, of the jaw *a*, there is fixed by two screws, a knob *d*, forming a quadrant whose centre is supposed to be at the centre of the rod. This quadrant is divided on each side of the dial, whose highest point is marked *h*, and the sweep would reach about 70° for the remainder of the arc down to 90° to be measured by the jaw. For two gradually plane are used as follows —

When the round rod towards *a* or *b* of the knob *d* is then vertical, and before to cut the table of the facet, or the point supports it on, and presses it to the table. On making it slope a little, *h* degrees for example, all the faces will now be on the same plane provided that the inclination be not allowed to vary. On turning round the round rod the index *g* marks the divisions so that by opening up the circle with 10 divisions, enough for some time at each 10 degrees will have been beyond of perfect equality, and at equal distances, as seen in the reference to engraving.

In cutting the stone, they are mounted on the round rod *a*, fig. 1077, whose axis is set upright in a socket placed at a middle of a sole piece at *x*, which receives the stem of the round-rod. The head of the tool is fixed into the top of *a*. A solid clay of tin and lead is poured into the head of the round-rod, at the point *h* of which the stone is immediately placed; and whenever the solder has become solid, a pressure of it is pushed off from the top of the diamond *d*, to give the perpendicular stroke in the figure at *u*.

There is an instrument employed by the watch-makers for pieces of clock work, and by the man-factory of watch-glasses for polishing their edges. It consists of a solid taken table fig. 1078. The top is perforated with

two holes, one for passing through the pulley and the arbor of the wheel plate *a* made either of lead or of hard wood, according to circumstances; and the other *c* for receiving the upper part of the arbor of the large pulley *t*. The upper pulley of the wheel plate is supported by an iron prop *r*, fixed to the table by two wooden screws. The inferior pivots of the two pieces are supported by screw-sinks, working in an iron screw nut sunk into the counter for *r*. The legs of the table are made longer or shorter, according as the workman chooses to stand or sit at his employment. Emery with oil is used for friending down, and tin putty or whetstone for polishing. The workman lays the piece on the flat of the wheel plate with one hand and presses it down with a lamp of cork, while he turns round the handle with the other hand. See the different cases under their respective heads.

LAPIS LAZULI. A silicate of soda, lime, and alumina, with the sulphide of iron and sodium in minute quantities. This beautiful mineral is found in crystalline limestone of a greyish colour, on the banks of the Indus, and is granite in Persia, China, and Siberia.

The finest varieties are highly esteemed, being employed in the manufacture of costly vases. It was also the source from which the beautiful pigment ultramarine was obtained, but this colour is now prepared artificially at a very cheap rate. See **ULTRAMARINE**.

LAPS. Metal polishing wheels. Metal wheels or laps made of nearly every metal and alloy in common use, have been more or less employed in the mechanical arts as vehicles for the application of several of the polishing powders. But of all types, notwithstanding their variety, those of lead, slightly alloyed, and supported with powdered emery, render the most conspicuous service. Generally the plane, or flat surface

of the lap, is employed; at other times the cylindrical edge, as by cutlers; but the portion actually used in either case is called the *face* of the lap. There are several kinds of laps. The lap is in some cases a thin disc of metal, fixed by means of a screwed nut against a shoulder on the spindle, but it is better with lead laps to employ an iron plate cast full of holes, to support the softer metal. The casting would vary in this case be either an iron disc, with a central screw to fix the iron centre plate at the time of pouring, or the mould may be made of sand and in halves, after the usual manner of the foundry. In either case the iron plate should be made as hot as the fluid metal, which, by entering the holes, becomes firmly united to the iron, especially if the holes are largest on the reverse side, or that away from the lead.—*Illustr. &c.*

Lap is also a roll of paper or cotton for feeding the cards of a spinning machine.

LARD. The fat of the pig. Our imports from the United States have been in 1857.—

	Cents.	Computed real value.
In British vessels - -	80,507	
In Foreign vessels - -	129,158	
	169,795	£561,944

LARD OIL. Lard being subjected to pressure, an oil, *oleine*, is expressed, *stearine* being left. The lard oil is much used for lubricating machinery, and it was employed for the adulteration of olive oil.

LAPIDS. All Indian cut stones are called *lapids*. They are in general all shaped or irregular in their form, their depth ill proportioned. The table, or face, which is in the centre of the stone, sometimes too broad or too small, and none properly polished. The chief thing regarded is making the size and weight of the stone. These stones are always new wrought when brought to Europe.

LATH WOOD. The outside cuttings of fir trees, used for being split into laths.

LATTEN is a somewhat antiquated term, which was applied to several kinds of sheet metal. "Mines of *latten*, whatever may have been meant by the word are mentioned in the time of Henry VI., who made his chaplain, John Botteright, comptroller of all his mines of gold, silver, copper, *latten*, lead, within the counties of Devon and Cornwall." Is tin meant by the term?—*Watson's Chemical Essays*.

In the reigns of Henry VIII. and Edward VI., several acts of parliament were passed, prohibiting the exportation of brass, copper, *latten*, bell metal, gun metal, schrof metal, &c. Windows framed with lead are called *lattice* windows in the West of England.

The term is now applied to sheet or plate brass. *Black latten* is rolled sheets; *alloy latten* is in thinner sheets, and *roll latten* is polished on both sides.

LAUNDER. A miner's term for a wooden tube or gutter to convey water. A long shallow trough carrying off the ore from the stamps.

LAVA. The ejected matter of volcanoes. "The stone which flows in a melted state from a volcano." (*Lyeil*.) M. Alach obtained from the lava of 1669, 48.83 silica. He made the lava to consist of 54.80 labradorite, 34.16 augite, 7.98 olivine, and 3.08 magnetic iron.

Buschhoff gives the following two analyses of lava:—

	Horta.	Kina.
Silica - - - - -	54.76	49.63
Alumina - - - - -	15.61	23.47
Peroxide of iron - - -	15.60	10.50
Lime - - - - -	6.14	9.05
Magnesia - - - - -	1.35	2.68
Potash - - - - -	3.41	3.07
Soda - - - - -	1.21	0.98

LAVA WARE. A peculiar stoneware, manufactured and coloured to assume the semi-vitreous appearance of lava.

LAVER. *Nephrya larinabi* and *Ilva latissima*. (See **ALGÆ**.)

LAVENDER, oil of. See **PURPURET**.

From the flowers of the *Lavandula spicata* the oil of spike is obtained, which is used by painters on porcelain, and by artists in the preparation of some varnishes.

LAWN. A fine linen fabric.

LAZULITE (Eng. and Fr.; *Lazulith*, Germ.), from an Arabic word, *azul*, meaning *azure*. It is a blue vitreous mineral, found massive and crystalline, traversing clay slate, and sometimes united with spathic iron; spec. grav. 2.76 to 2.94; scratches glass; affords a little water by calcination; fusable into a white glass; dissolves in

acids with loss of volatile, the residue leaves an all-siliceous residuum, after being treated with carbonates of ammonia, filtered, evaporated and calcined. By analysis it is found to consist of:—

	1.	2.
Phosphoric acid	43.44 . . .	46.78
Alumina	31.77 . . .	37.11
Iron oxide of iron	9.00 . . .	7.10
Magnesia	9.00 . . .	11.07
Water	1.00 . . .	7.12

LEAD. (*Plumb.* Fr.; *Blitz.* Germ.) This metal appears to have been known at a very early period. It is mentioned by Moses as a metal in common use. Job describes mining for lead, and the metal is in evidence of religious and domestic uses from lead are very fully described by both Job and Jeremiah. Lead has a bluish-grey colour, and, when freshly cut, it is of a considerable lustre, which, however, it speedily loses. It is one of the softest of the primary metals, it may cut with a knife, may be scratched with the nail, and marks paper with a grey stain. Lead is malleable, and may be beaten into thin leaves, but there are of very important property; hence, it cannot be drawn into thin wire; a wire of $\frac{1}{8}$ of an inch in diameter will not support 20 lbs.

If lead be prepared in a very finely divided state, it is pyrophoric. This is usually prepared from the tartrate of lead, by heating it in a glass tube as long as any fumes are evolved, consequently it is finely divided lead covered with some carbon. As soon as the fumes cease the tube must be closed at the blow-pipe-lance. If at any time the tube is broken, and the powder scattered in the air, it burns with a red flame.

If lead is heated in closed vessels it fuses at 600° F. (315° Cent.), and at a red heat it gives off vapours. If fused lead is allowed to cool slowly, it crystallizes in a somewhat peculiar manner, the crystals are regular in the crystalline system, but they group themselves in a very singular and interesting way. By the electro-chemical action of zinc on a solution of the acetate of lead, crystals of that metal are obtained in an arborescent form. This experiment is usually performed as the formation of Saturn's tree, Saturn being the alchemical name for this metal.

When fused in the air, lead oxidizes rapidly, and it becomes covered with an iridescent pellicle, often of great beauty. It then passes into a yellow powder (1. barge), composed of lead.

Pure lead is not affected by perfectly pure water for ever, but if air be present the metal is oxidized at its exposure, and the oxide thus formed, combining with carbonic acid, is deposited on the lead in minute crystals of a black substance of lead. The water will then be found to contain lead in solution, and such waters drawn from impure cisterns often produce very distressing consequences. If the water contains any sulphates, the lead is thrown down as a sulphate of lead, which is insoluble.

The native formations are the following. The localities, &c., are mainly derived from Greg and Lettison's *Manual of the Mineralogy of Great Britain and Ireland*.

1. *Native lead.* Mr Greg appears to doubt the existence of native lead in this country. He says, however, "Native lead has been recently discovered in unaltered granine specimens in the province of Guanajuato in Mexico." Some equally genuine specimens of native lead have been found in the Grassington mines; these are in the possession of the Duke of Devonshire and of Stephen Lidd, Esq.

2. *Minium.* *Native oxide of lead.* This ore is found in Angleson, at Alton Moor, the Scaifbeach Mine in Shropshire, at Grassington, the Leadhills in Scotland, and Wicklow in Ireland. Its composition is—lead, 90.6; oxygen, 9.4.

3. *Cerussite.* *Carbonate of lead.* This ore occurs in crystals, in fibrous, compact, and earthy masses. It is found at several of the lead mines of Cornwall and Devonshire, and indeed in nearly all the mines producing the ores of lead, varying much in its character with the different conditions under which it has been formed.

This ore, in its purest state, is colourless and transparent like glass, with an adamantine lustre. It may be recognized by the following characters:

Its specific gravity is from 6 to 6.7; it dissolves with more or less ease, and with effervescence, in nitric acid; becomes immediately black by the action of sulphuric acid and hydrogen, and melts on charcoal before the blow-pipe into a button of lead. According to Klaproth, the carbonate of Leadhills contains 82 parts of oxide of lead, and 16 of carbonic acid, in 98 parts. This mineral is tender, scarcely scratches calc-spar, and breaks easily with a waved conchoidal fracture. It possesses the double refraction property in a very high degree—the double image being very visible on looking through the flat faces of the prismatic crystals. Its crystalline forms are very numerous, and are referrible to the rhombohedron.

4. *Anglesite.* *Sulphate of lead, or Vitreous lead.*—This mineral closely resembles cer-

bonate of lead; so that the external characters are not much to be relied on. The following are the characters. When pure, the mineral is perfectly white. It does not effervesce with nitric acid, it is but feebly soluble in aqua regia; it fuses with difficulty, and then becomes milky as it cools. It is composed of a mixture of lead and cerium, the former first in amount, and the latter in metallic value, according to Klaproth, of 71 parts of lead, 28 sulphuric acid, 2 water, and 1 iron. The specimen was from Australia, the Wackhead mineral is from France. The principal form of crystals is the rectangular octahedron, with angles and edges are variously modified. This mineral was first recognized in Australia, hence its name. It was found in the Cornish lode at Park mine, and is usually met with in the Lead Hills and Wackhead in Scotland, at Glenside in Wexford, and at the Cornish mine, in Idaho.

Leadhillite. Sublimatory elements of lead.—This ore is of a yellowish white color, becoming grey, or sometimes yellowish-green, yellow and brown. Its composition is —

Sulphate of lead	-	-	-	-	-	-	347
Carbonate of lead	-	-	-	-	-	-	710
							<u>907</u>

6. *Phosphorites*.—The phosphate of lead.—This, like all the phosphates of lead with arsenic, exhibits a metallic lustre, but a variety of colours. Before the blow pipe, upon charcoal, it runs into a glassy externally crystalline, which by a roasting process of the heat, with the addition of iron and borax, acquires a vitreous lead. Its composition is 60 parts of lead, 14 phosphoric acid, and 16 hydrochloric acid, according to Klaproth's analysis of the mineral from Walshead. The arsenic is present. Of chlorine in the various specimens examined is a very remarkable circumstance. The crystalline forms are derived from an oblique rhomboid. Phosphate of lead is a little harder than white lead; it is easily scratched, and its powder is always gray. Its specific gravity is 6.9. It has a vitreous lustre, somewhat adamantine. Its texture is not very distinct, its fracture is wavy, and it is easily fragile. The phosphoric and arsenic, in a long, according to M. Mitscherlich, isomorphous bodies, may replace each other in chemical combinations in every proportion, so that the phosphate of lead may include any proportion, from the smallest fraction, of arsenic acid, to the smallest fraction of phosphoric acid, thus graduating infinitely into arsenate of lead. The yellowish variety indicates, for the most part, the presence of arsenic acid. It is found in Cornwall, Devonshire, Yorkshire, and Derbyshire.

6 *Mimetic Arsenite of lead*—The vein is derived from pyrites, and is composed of nearly resembling pyromorphite. The colour of it is ore rather than a brownish yellow and was yellow to brown, reddish-brown, orange, yellow, and red like the blow-pipe, charcoal, it contains arsenical fumes and yields a load of lead. The analysis by Dufrenoy gives the following as its composition—

Acetate of lead	-	-	-	-	-	-	14 55
Phosphate of lead	-	-	-	-	-	-	4 50
Chloride of lead	-	-	-	-	-	-	9 05

At Drygal, in Cumberland, this ore has been met with in sufficient abundance to be worked to some extent as an ore of lead. The mimette from this mine was used in the manufacture of flint glass, in which it gave great brilliancy. The form of the arsenate of lead, when it is crystallised, is a prism with six faces, of nearly the same dimensions as that of phosphate of lead. When pure, it is reducible upon charcoal, in fire the blow-pipe, into metallic lead, with the copious exhalation of arsenical fumes; but only in part, and leaving a crystalline globule, when it contains any phosphate of lead. The arseniate of lead is tender, friable, sometimes even pulverulent, and of specific gravity 8.04. That of Johann-Georgenstadt consists, according to Rose, of oxide of lead, 77.51; arsenic acid, 12.31; phosphoric acid, 7.5; and chlorine, 1.5.

7. *Galena*. *Sulphide of lead*.—This is the most abundant ore of lead; it may be indeed regarded as the only commercial ore of any value, if we except the carbonates which are probably formed by the decomposition of galena. Its prevailing forms are the cube and a combination of the cube and octahedron; lustre metallic, opaque, colour and streak lead grey. Fracture conchoidal, but difficult to obtain, owing to the readiness with which it cleaves. The localities of galena need not be named here, as the lead producing districts, of which a list will be presently given, will include them, and galena is included in them all. Thomson's analysis of galena gives—

Lead	-	-	-	-	-	-	65.13
Iron	-	-	-	-	-	-	0.50
Sulphur	-	-	-	-	-	-	13.02

a. Jasmundite is a combination of lead and antimony. It occurs in acicular crystals, as in parallel or diverging groups, and very frequently in fibrous masses. It is found in many places in Cornwall and Devon. Hume's analysis gives the following as its composition:—

Lead	87.71
Iron	2.95
Copper	0.51
Zinc	0.74
Antimony	8.98
Sulphur	2.09

100.00

This mineral may be regarded as a double sulphide of lead and antimony, analogous to the double sulphide of copper and iron.

b. Crocoisite. Chromate of lead. Horn lead, or chloro-chromate.—This ore has a pale yellow colour, is reducible to metallic lead by the action of acids, and is not altered by the hydro-sulphuric. Before the blow-pipe it melts into a pale yellow translucent glass, with salt of phosphorus and oxide of copper, and assumes the prismatic character. It is fragile, and, after than (or much) of lead, and is sometimes a more beautiful white adamantine lustre. Sp. grav. 6.06. Its composition, according to Berthier, are, lead, 87.4; oxide of lead, 7.07; carbonate of lead, 0.95; chlorine, 0.44; silica, 1.43; water, 0.54, in 100 parts.

10. *Plumbite. Superoxide of lead.*
11. *Limonite. Cuprous sulphate of lead.*
12. *Sulphate. Sulphate-trisulphate of lead.*
13. *Limonite. Sulphate-trisulphate of lead.*
14. *Chalcocite. Cuprous sulphate-trisulphate of lead.*
15. *Limonite. Vanadate of lead.*
16. *Wulfenite. Tungstate of lead.*
17. *Stilbite. Molybdate of lead.*
18. *Geocrinite. Sulphide of lead and antimony.*
19. *Manganite. an Oxysulphate of lead.*
20. *Malachite. ditto.*

21. *Red lead, or Chromate of lead.*—This mineral is too rare to require consideration in the present work.

22. *Plomb Vauquelinite. Chromate of lead and copper.*

The ores of lead, which may be represented by galena, or the sulphide of lead, that being the truly commercial variety, are found in rocks of different ages from the granite and clay slates to the triassic formations. In the Devonian slate rocks, in the neighbourhood of Liskeard in Cornwall are many most productive lead mines. To the north of Truro is the lead mine Huel Rose, which has from its long celebrity given its name to the district; and again to the south of Helstone there have been some valuable workings for lead. These formations of lead ore have all been in the clay slate, "killas" rocks of Cornwall. In Devonshire many most valuable lead mines have been worked in similar rocks. In these the celebrated mines of Beer Alston on the Tamar exist. With a very few exceptions but little lead has been discovered in the black slates,—the carboniferous series of Devonshire. Some lead ore has, however, been discovered in the new red sandstone and in the slate rocks immediately adjoining them near Newton St. Cyren. To the north of the carboniferous rocks of Devonshire we have a renewal of clay slate rocks, similar in all respects to those which are found near Liskeard in Cornwall; in these rocks are the most famous argenteiferous lead mines of Combe Martin, from which Edward the Black Prince derived an immense revenue.

The lead mines of the Mendip Hills which were at one time very productive, but which are now producing but small quantities of lead ore, are in the mountain limestone formations. Those of Cardiganshire are found in clay-slates and gritstones, corresponding with or underlying the lowest beds described by Sir R. Murchison in his Silurian System. — *Seyth.*

In Shropshire we have lead ore occurring in the original silurian rocks, the Llanfyllid formation. "In that lofty and rugged district of Shropshire which lies around the village of Shelve and the Cornhill mountains, and which extends west of the Sugar Stones range into Montgomeryshire" (Murchison), lead lodes are abundant. In Derbyshire, in Yorkshire, in Cumberland, Northumberland, and Durham, the lead mines prove the most productive in the mountain limestone formations, although they are some instances in which good lead mines have been worked in the sandstones and shales. In addition to these, we have the mines in the Leadhills and at Wanlock-

head, consisting chiefly of the graywacke slates, in Scotland. In Lough Erne, in the granite districts of Wicklow, Newlands in County Down, with a few others in Ireland, and the lead mines in the Slieve Donard of the Isle of Man. These are the principal districts from which our large supplies of lead ore are obtained.

The extensive lead mines of Mr. Menzies, which have for many years produced about one-fourth of the quantity raised in England, about one-sixth of the produce of Great Britain, and about one-tenth of that of the whole of Europe, including the British Isles, are so important, and in many respects so characteristic, that much of the description of them which appeared in the former edition is retained, as representing many of the principal and important features of lead mining. An extensive series of the great lead mining district is in the Mining Record Office of the Museum of Practical Geology. This section was executed by Mr. Sopwith, and together with a series of models explains nearly all the phenomena of mineral veins.

The datum or base line of the Allenheads section is 700 feet above the level of the sea. The drawing, 16½ feet in length, is on a true scale of 1½ feet to an inch; by a true scale being meant, that the lengths and breadths are projected to the scale or proportion, so that a true miniature profile of the country is given, as well as a correct reduction of the relative size of the various rocks. The extent of country thus shown is not quite 4 miles, being 3 miles 1,225 yards.

The spectator is supposed to be looking to the north, and the section commences at a point about half a mile seaward from a place called Kilhope Head, which is conspicuously marked in all English maps, as such as the three counties of Northumberland, Durham, and Cumberland here meet in one spot. At about three quarters of a mile from this point of commencement, the section represents the hill called Kilhope Law; it is on the boundary line of the counties of Northumberland and Durham, and is the highest point of land in the last-named county, being 2206 feet above the level of the sea. Just out of the limits of this section, and about 10 miles south-west from Kilhope Law, the same strata which are here delineated reach an altitude of 2901 feet above the sea, and this is the highest elevation attained by the rocks which form the carboniferous or mountain limestone of the north of England.

Such being the stratification of the central portion of the narrow part of the island, of which the coal fields of the Tyne and Wear form the extremity on the east bordering the German Ocean, for some distance north and south of Newcastle, while a similar coal field is found at the western extremity near Whitehaven, it may be observed with reference to these coal fields, that they lie over or upon the mountain limestone formation. The coal beds so extensively worked in the Newcastle and Durham coal mines or collieries gradually rise to the west, and one by one crop out or burst according to the undulations of the country. At length at about 20 miles west of the German Sea, the lowest of the coal beds crops out, and from beneath it gradually appear the limestone strata, which continue to rise nearly coincident with the general rise of the country, until they reach the summit of Cross Fell (2901 feet). This general and very gradual inclination of the strata, a feature of the greatest importance in practical mining, is clearly and accurately delineated in this section.

In a thickness of about 2000 feet of the alternating beds of sandstone, clay, and limestone which form the strata of the mining districts of Allendale, Alston, and Weardale, there is one single stratum of limestone, called the "great limestone," the veins in which have produced nearly, if not quite, as much ore as all the other strata put together. This stratum, delineated in the section, lies at a depth of about 650 feet below the summit of Kilhope Law. Somewhat exceeding 2 miles eastward of this, at Allenheads, the top of the great limestone is 230 feet from the top of a shaft called Gun-Hill Shaft. Its thickness, which is tolerably uniform over several hundred square miles of country, is about 60 feet; and it is in this stratum of limestone that the largest quantity of lead has been found.

The dislocations of strata which constitute for the most part important mineral veins, are exhibited more in detail in the series of geological models already referred to.

At about a quarter of a mile to the west of, or left hand direction from Kilhope Law, the great limestone, and all other associated beds are thrown down a depth of about 100 feet for a space of nearly 700 feet; and again, at the distance of nearly a mile from Allenheads, a vast dislocation takes place, by which the great limestone is brought nearly to the surface, the amount of displacement being about 400 feet. It is in the great limestone that by far the most extensive portion of the workings of Allenheads lead mines are situated, and the galleries or levels are very extensive. In a great thickness of strata above the great limestone, only two beds of that rock are found. One of these is called "little limestone." It is from 10 to 12 feet thick, and is 75 feet above the top of the great limestone. The other is still more inconsiderable, being only 3 or 4 feet thick, and is 440 feet above the great

however. It is remarkable, with what exactness this thin bed is found near the surface of hills, the intervening spaces having apparently been removed by denudation, so as to form in this case a gap of 41 miles, and in another of 11 miles, in which the Tint Tpl. limestone is entirely cut off.

But besides the great mine, are several beds of the same description of rock, viz. at distances respectively of 30, 100, 150, 250, and 27 feet, and the thicknesses 2 ft. 1 in., 1 ft., and 15 in. These are known by descriptive local names, and some price all that are of a richness as regards lead mining operations.

The Alameda mine being situated for the most part at the base of the position varying from 100 to 200 feet are drilled, partly by ordinary water-wheels, and partly by hydraulic engines constructed by Mr. New Sir W. G. Armstrong. See WATER INSTEAD OF ELECTRICITY.

Such is a general view of the lead mining district of England. The following brief account of foreign lead mines is intended merely for last reference. Much additional information will be found in the article Mines.

The principal lead mines at present worked in other parts of the world are the following:—1. Poullouen and Huelgoat, near Carhaix in France, department Finistère, being veins of galena, which traverse a clay shale resting in granite. They have long been known for upwards of three centuries; the workings penetrate to a depth of upwards of 100 yards, and in 1816, furnished 500 tons of lead per annum, out of which 100 tons of silver were attracted. 2. At Valdivia and Valdivia, department of La Oroya, are galena mines said to produce 100 tons of lead per annum, 400 kilograms of silver (880 lbs. avoirdupois). 3. At Potosí and Moravia, the best of Moravia in Saxony, a galena mine extends to a depth which has produced annually 200 tons of lead, and about 600 kilograms of silver (1320 lbs. avoirdupois). 4. The mine of Vedrina near Salsburg in the Lower Saxony, is reported upon a vein of galena, traversing compact limestone of a transition district; it has furnished 700 tons of lead, from which 100 pounds avoirdupois of silver were extracted. 5. In Saxony the galena mines are of such a silver as to make the lead almost worthless. They are considered under silver veins. 6. The lead mines of the Harz have been likewise considered as silver ones. 7. Those of Huelgoat in the Harz, are of the same kind. 8. The galena mines of Huelgoat and Valdivia in Carinthia, are compact limestone. 9. In Bohemia in the south-west of Prague. 10. Mines of Joachimsthal and Freiberg in the southern slope of the Erzgebirge, produce a galena of the same kind. 11. There are numerous lead mines in Spain, the most important being in the granite hills of Linares, upon the eastern slope of the Sierra Morena, and in the district of the small town of Cañete. In these countries galena mines of galena are extracted from the mines of Linares. There are also mines of galena in Castile, Granada, Murcia, and Almería, the ore of the last locality being generally poor in silver. 12. The lead mines of Sweden are very argentiferous, and worked chiefly with a view to the silver. 13. The lead mines of Prussia are numerous and rich, lying in a transition limestone, which rests on primitive rocks; their lead is neglected on account of the silver.

There have been a few lead mines in this country, which have been equally productive of silver. This was especially the case with the lead mines which were formerly worked around Combe Martin, and those at Heer-Alston in Devonshire. One of the most remarkable of recent examples, is a small mine known as Hill Florence near Tavistock, from which some lead ore has been sold at upwards of 50s. a ton, on account of the large quantity of silver it contained. At the conclusion of this article some tables will be given, showing the argentiferous character of the different lead producing districts of the United Kingdom.

Before proceeding to the consideration of the metallurgy of lead, a few brief notices of the history of lead mining may not be out of place.

As we have already stated, mining for lead must have been one of the earliest of man's subterranean labours, and at all periods of history we learn that lead mines have been worked. The Romans, especially, worked lead mines in Spain, and, after the conquest of this country, in many of our lead producing districts, especially in Cardiganshire, Shropshire, and Flintshire.

Lead mining appears to have been carried on from a very early period in Alston Moor, and some other of the northern districts. But in the west of England, lead mining must be regarded as a somewhat recent industry.

"Horlase mentions, in 1754, that lead mines had plentifully and lately been worked in Cornwall, and that those most noted formerly, were Penryn, Poughilly, Trevenno, Huelgoat, and Guarnick (Garras). He states, that Penryn mine (near Huelgoat) had been wrought for about 200 years, that is, from about the middle of the sixteenth century, and that they had yielded tolerable profit within thirty years. The only lead mine worthy of note at work in his time, was at St. Isey, near Padstow. Pryce,

describes the lead ore of Garra, near Truro, to have been so argentiferous, that when wrought about 1720, it produced 100 oz. of silver in the ton of lead. Huel Pool, near Illogan, about 1790, yielded from 40 to 80 oz. of silver per ton of lead, and works were erected for extracting the silver. The lead ore of Wheal Rose contained 60 oz. of silver per ton.

In Devonshire, the Combe Martin and Beer Alston mines, have long been celebrated for their argentiferous lead ores. It is stated, that the produce of these mines was unusually great in the reigns of Edward I. and Edward II. In 1293, William de Wyntonham accounted at the Treasury for 270 lbs. of silver raised in Devon. In 1294, it amounted to 521*l.* 10*s.* weight; and in 1294, to 704*l.* 3*s.* 1*d.* weight. In 1294, great profit is stated to have been derived from the Devon mines; and 360 miners were impressed out of Derbyshire and Wales to work in them. In 1340, a writ was issued, authorising certain persons to take up as many miners and workmen as should be necessary to work in the king's mines in Devon, allowing them reasonable wages according to the custom of the country; to arrest and imprison such as should resist, till they should give security to serve the king in the said mines, and to buy and provide timber at a competent price.

Henry, bishop of Winchester and cardinal of England, as one of the executors of John, duke of Bedford, who had a grant from the King of the gold and silver mines of Devon and Cornwall, rendered 26 lbs. and 2 oz. weight of pure silver as the 15th part of the pure silver raised in those counties from 15th December, 21st, to 15th August, 23rd of the same king's reign.

The Combe Martin mines were re-opened in the reign of Elizabeth. The working of these mines was strongly recommended to the Long Parliament in 1632; but Lysons observes that they do not appear to have been again worked until the close of that century, and then without success. In 1813 they were again opened and worked for 4 years, producing only 208 tons of ore in that time. In 1837 they were again worked, and we had an opportunity of observing that the previous mining operations presented every appearance of having formerly been very unskillfully managed. The two lodes near Beer-Alston have produced large quantities of argentiferous galena, often containing from 80 to 120 oz. of silver per ton of lead. According to Mr. Hitchings, the greatest quantity which occurred in that part of them named the South Hooe mine was 140 oz. of silver per ton of lead. In 1784 and 1785 the silver produce of these mines amounted to 6500 oz. From Huel Betsy, near Tavistock, which was re-opened in 1804, from 300 to 400 tons of lead, and from 4000 to 5000 oz. of silver were annually obtained. Lead mines were worked at a very early period in the Isle of Man, but the recent workings only date from the commencement of the present century. The mines of Cheshire were evidently worked by the Romans. In the reigns of Henry VII. and of Elizabeth they attracted much attention, and German miners were invited to work them.

The English lead-miners distinguish three different kinds of deposits of lead ore; *rake-veins*, *pipe-veins*, and *flat-veins*. The English word *vein* corresponds to the French term *filon*; but miners make use of it indifferently in England and France, to indicate all the deposits of this ore, adding an epithet to distinguish the different forms; thus, *rake-veins* are true veins in the geological acceptation of the word *vein*; *pipe-veins* are masses usually very narrow, and of oblong shape, most frequently parallel to the plane of the rocky strata; and *flat-veins* are small beds of ores interposed in the middle of these strata.

In the north of England, which, on account of its great preponderance in produce, we take as the basis of our description of lead mining, the ores are for the most part found in *veins* (*lodes* in Cornish) and *flats*. Although different names have been assigned to occasional varieties, the usual occurrence of lead ore is in *rake veins*, or direct running veins, usually named as *veins*, with some distinctive appellation prefixed, as, for example, Rampgill Vein, Hudgillburn Vein. Other veins, lying parallel, receive a similar prefix, with the addition of the words north, east, or south; but for the last named the word *sun* is often used; as, for instance, Hudgillburn Sun Vein, and 2nd and 3rd Sun Vein if farther discoveries are made of other parallel veins. Considerable quantities of ore are also raised from horizontal extensions of portions of the vein called *flats*, and these are interposed between the strata adjacent to the vein.

Rake veins are the most common form in which lead ore occurs in Cumberland. They are in general narrower in the sandstone which covers the limestone, than in the calcareous beds. A thickness of less than 2 feet in the former becomes suddenly 3 or 4 feet in the latter; in the rich vein of Hudgillburn, the thickness is 17 feet in the Great limestone, while it does not exceed 3 feet in the overlying Waterfall or sandstone. This influence exercised on the veins by the nature of the enclosing rock, is instructive; it determines at the same time almost uniformly their richness in lead ore, an observation similar to what has been made in other countries, especially in the veins

Galena is, however, not seldom found chemically pure, as, in addition to variable quantities of earthy impurities, it almost always contains a certain amount of silver. It is usually observed that galena presenting large facettes is less argentiferous than those varieties having a closer grain, and that finely granular stony specimens generally afford the largest amount of silver.

It would appear, from recent experiments, that the silver contained in the finely-granular varieties of galena often occurs in the form of sulphide of silver, mechanically intermixed, whilst in the more flaky descriptions of this ore, the sulphides of lead and silver are intimately combined.

Galena occurs in beds and veins, in granite, gneiss, clay-slate, limestone, and sandstone rocks.

In Spain it is found in the granite hills of Lanarès and elsewhere; at Freiberg in Saxony it occupies veins in gneiss, in the Harz, Bohemia, Cornwall, and many other localities, it is found in kiesel, or clay slate. The rich deposits of Derbyshire, Cumberland, and the northern districts of England, are in the mountain limestone, whilst at Cammern, near Aix-la-Chapelle, large quantities of this ore are found disseminated in the Hunter sandstone.

This mineral is frequently associated with blende, iron and copper pyrites, the carbonate and other ores of lead, and usually occurs in a gangue of sulphate of baryta, calc-spar, spathose iron, or quartz. It is also not unfrequently associated with fluor-spar.

The next most important ore of lead is the carbonate, which is a brittle mineral, of a white or greyish-white colour, having a specific gravity varying from 6.46 to 6.60. Its composition is, —

Carbonic acid	16.05
Oxide of lead	89.56
							99.61

Large quantities of this substance occur in the mines of the Mississippi Valley in the United States of America, where they were formerly thrown away as useless, but have since been collected and smelted. Vast deposits of this substance have also been found in the Bunter sandstone, near Duren, in Prussia, and at Freyung, in Bavaria. In the two latter localities it appears to form the cement holding together the granules of quartz, of which the sandstone principally consists. These ores, which yield from 14 to 20 per cent. of metal, do not readily admit of being concentrated by washing.

The sulphate of lead does not often occur in sufficient quantities to be employed as an ore of that metal. In appearance it is not unlike the carbonate, but may readily be distinguished from it by its not dissolving with effervescence in nitric acid.

Its specific gravity is from 6.25 to 6.50, and its composition —

Sulphuric acid	25.45
Oxide of lead	74.05
							99.70

This ore of lead usually results from the oxidation of galena. At St. Martin's, near the Vega de Ribadeno, in Spain, this mineral, more or less mixed with the phosphate of lead, is found in sufficient quantities to be made, on a small scale, the subject of an especial metallurgic treatment. Large quantities of sulphate of lead ores are also annually imported into this country from the mines in Australia. These ores contain on an average 35 per cent. of lead, and 35 oz. of silver to the ton of ore, together with a little gold.

Phosphate of lead, when crystallised, usually presents the appearance of hexagonal prisms, of a bright-green, brown, or yellowish colour. Its specific gravity varies from 6.3 to 7.1. This mineral is composed of a mixture of true phosphate of lead, phosphate of lime, chloride of lead, and fluoride of calcium, and usually contains about 75 per cent. of oxide of lead. In Spain, it occurs in botryoidal forms, in connection with the sulphate of the same metal, and is treated in blast furnaces for the lead it affords.

The other minerals containing lead seldom occur in sufficient quantities to be of much importance to the smelter, and may therefore be disregarded in the present article.

The extraction and mechanical preparation of ores is the business of the miner, and not of the metallurgist who receives them from the former freed as perfectly as possible from foreign matters.

The metallurgic processes, by the aid of which lead is obtained from galena, may be divided into two classes. The first of these is founded on the following reactions: — If one equivalent of sulphide of lead and two equivalents of the oxide of the same

metal are fused together, the result is three equivalents of metallic lead and one equivalent of sulphurous acid, which is evolved.

This reaction is represented by the following equation:—

When, on the other hand, one equivalent of sulphide of lead and one equivalent of sulphate of lead are similarly treated, two equivalents of lead are obtained, and two equivalents of sulphurous acid are evolved. Thus:—

The process, founded on the foregoing reaction, and which we will distinguish as the method by double decomposition, consists in roasting the galena in a reverberatory furnace until a certain amount of oxide and sulphate has been formed, and then immediately, after having thoroughly stirred the charge, and closed the doors of the furnace, causing the whole to enter into a state of fusion.

During this second stage of the operation, the reaction between the sulphide, sulphates, and oxides takes place, and metallic lead is produced. The reaction of the ore is, in some cases, conducted in the same furnace in which the fusion is effected, whilst in others two separate furnaces are employed.

The process by double decomposition is best adapted for the richer varieties of ore, and such as are least contaminated by siliceous or earthy impurities, and is consequently that which is also at present generally employed for smelting the ore of this country.

By the second method which we will call the process by fusion, the ore is fused with a mixture of metallic iron, which by combining with the sulphur liberates the metallic lead. This reaction will be represented by symbols in the following formula:—

In practice, however, metallic iron is not always employed for this purpose; cast-iron is also frequently used, and it sometimes is the ore of iron and copper slag are employed, as are also tap-cinder and other secondary products containing a considerable percentage of this metal. None of these substances are, however, found to be so efficacious as metallic iron, since cast-iron requires to be decarburised before it can really decompose the sulphide of lead, and the ores of iron require the introduction of various fluxes, and the consequent expenditure of a substantial amount of fuel. In all cases, however, it is justifiable to subject the ore to a preliminary roasting, in order to eliminate a portion of the sulphur, and thereby reduce the expenditure of iron, as well as to agglutinate the ore and render it better adapted for the subsequent treatment in the blast furnace.

We will not attempt to describe the different forms given to roasting furnaces employed for the ores treated by this process, but would remark that they frequently resemble the kilns used for the preparation of lime, whilst in some instances the ores are roasted in heaps interstratified with wood or other fuel.

The method of treating ore by affinity is particularly adapted to those varieties that contain a considerable amount of silica, since such minerals, if treated by double decomposition, would, by the formation of oxide of lead, give rise to a slag from which it would be exceedingly difficult to extract the metal.

English process. Treatment by double decomposition.—Galena, if placed in a close vessel which protects it from the action of the air, and exposed to a gradually increasing temperature, becomes fused without the elimination of any lead taking place, but ultimately a portion of the sulphur is driven off, and a sulphide is formed, which at a very elevated temperature is volatilised without change.

If, however, the vessel be uncovered, and the air allowed to act on its contents, oxygen combines with the sulphur, sulphurous acid is evolved, and the decomposition of the mineral is slowly effected.

When galena is spread on the hearth of a reverberatory furnace, and is so placed as to present the largest possible amount of surface to oxidising influences, it will be found that the surface slowly becomes covered with a yellowish-white crust of sulphate of lead. The oxygen of the air, by combining with the two elementary bodies of which galena is composed, will evidently produce this effect. This is not, however, the really chemical change which takes place in the charge under these circumstances; oxide of lead is produced at the same time as the sulphate, or rather the formation of the oxide is prior to that of the sulphate.

In fact, during the first stage of the operation of roasting, sulphurous acid is evolved, the sulphur quits the lead, and a portion of that metal remains in a free state. This becomes oxidised by the air passing through the furnace, and subsequently a part of it combines with sulphuric acid, formed by the oxidation of sulphur.

rous acid, and sulphate of lead is the result. In this way, after the expiration of a certain period, both oxide and sulphate of lead are present in the furnace.

During the early period of the roasting, when the temperature of the furnace is not very elevated, the proportion of sulphate is larger than that of the oxide formed, but in proportion as the heat of the apparatus increases, the production of oxide becomes more considerable, whilst that of the sulphate diminishes.

The sulphate and oxide then succeed to react in their turn on the undecomposed galena, whilst a portion of the latter, by combining with the sulphide of lead, gives rise to the formation of oxide lead.

This last compound has no action on galena, except to dissolve it in certain proportions, but is readily decomposed by the aid of carbonaceous matter.

It is therefore evident that the addition of carbon, at this stage of the operation, will have the effect of reducing the oxide and oxysulphide of lead.

Every process then that has for its object the reduction of lead ores by double decomposition, comprises two principal operations. 1st. The reduction of galena, by the aid of heat and atmospheric air, to a mixture of sulphide, oxide and sulphate, which mutually decompose each other, with the elimination of metallic lead. 2nd. The reduction of the oxysulphide by the addition of carbonaceous matter.

The reverberatory furnace.—The reverberatory furnace employed for the treatment of galena is composed, like all other furnaces of this description, of three distinct parts, the fire-place, the hearth, and the chimney.

The hearth has to a certain extent the form of a funnel, of which the lowest point is on the front side of the furnace immediately below the middle door. The molten metal descending from every side along the inclined bottom or sole, is collected in this receptacle, and is ultimately run off by means of a proper tap-hole. This tap-hole is, during the operation, closed by a jet of clay.

The inclination of the hearth is more rapid in the vicinity of the fire-bridge than towards the chimney, in order that the liquid metal may not be too long exposed to the oxidizing and volatilizing influences of a current of strongly-heated air.

The dimensions given to these furnaces, as well as the weight of the charge operated on at one time, vary considerably in different localities, but in the north of England the following measurements are usually employed:—The fire-grate is 3 ft. 9 in. x 1 ft. 10 in., and the thickness of the fire-bridge 1 ft. 6 in.; the length of the sole is 9 ft., and its average width 7 ft. The depth of the tap is about 2 ft. 6 in. below the top of the inclined sole. The height of the roof at the fire-end may be 1 ft. 4 in., and at the other extremity 11 inches.

The introduction of the charge is in some cases effected by the doors of the furnace, whilst in other instances a hopper, placed over the centre of the arch, is made use of.

On the two sides of the furnace are placed three doors about 11 in. x 9 in., which are distinguished as 1, 2 and 3, counting from the fire-bridge end. The three doors on the one side are known as the front-doors, whilst those on the other side are called the back-doors. Immediately beneath the door on the front side of the furnace is situated the iron pan into which the molten lead is tapped off.

The bottom of this arrangement is in most cases composed of fire-bricks, covered by a layer of vitrified slags, of greater or less thickness. In order to form this bottom, the slags are introduced into the furnace, the doors closed, and the damper raised. An elevated temperature is thus quickly obtained, and as soon as the scorie have become sufficiently fused, they are, by means of rakes and paddles, made to assume the required form. The charge employed, as before stated, varies in almost every locality. In the North, however, smaller charges are used than most other localities. At Newcastle, and in the neighbourhood, the charge varies from 12 to 14 cwt.; in Wales, and near Bristol, 21 cwt. charges are treated; whilst in Cornwall, charges of 30 cwt. are not unfrequently worked. The time required for smelting a charge varies with its weight and the nature of the ore, from 6 to 24 hours.

In some cases the ore is introduced raw into the furnace, whilst in others it undergoes a preliminary roasting previous to its introduction. Rich ores are generally smelted without being first calcined, but the poorer varieties, and particularly those which contain large quantities of iron pyrites, are, in most instances, subjected to roasting in a separate furnace.

In order to understand more clearly the operation of smelting in furnaces of this description, we will suppose that a charge has just been tapped off, and that, after the usual clearing the hearth, a fresh charge of raw ores has been introduced. During the first part of the operation of roasting, which usually occupies about two hours, the doors are taken off to admit free access of air, and also for the purpose of cooling the furnace, which has been strongly heated at the close of the preceding operation. No fuel is at this period charged upon the grate, since the heat of the furnace is of itself sufficient to effect the elimination of the first portions of sulphur.

ores to be smelted. This furnace has no hole for running off the slag, above the level of the tap hole for the lead, like the smelting furnace of Lea, near Matlock. A single chimney stack serves for all the castles; and receives all the fumes of the various roasting and smelting furnaces. Fig. 1081 gives an idea of the distribution of these flues. *a a a*, &c. are the furnaces; *b*, the flue, 18 in. hex. square; these lead from each furnace to the principal conduit *c*, which is five feet deep by 2½ wide; *d* is 4 feet deep by 3 wide; *e* is a round chamber 12 feet in diameter; *f* is a conduit, 7 feet high by 5 wide; *g* another, 6 feet high by 3 wide. The chimney at *A* has a diameter at bottom of 10 feet, at top of 12 feet, including the thickness of its sides, forming a truncated cone 100 feet high, which stands upon a hill a little way from the furnace, and 60 feet above their level.

a, the grate; *b*, the door of the fire-place; *c*, the fire-bridge; *d*, the arched roof; *e*, the hearth; *f f f*, &c. the working doors; *g g*, flues running into

conduit, which leads to the subterranean condensing-chamber *e*, and thence to the general chimney *y*; *A*, a hopper-shaped opening in the top of the furnace, for supplying it with ore.

This magnificent structure is not destined solely for the reduction of the ores, but also for dumping all the vapours which might prove noxious to the health of the workpeople and to vegetation.

The ores smelted at Holywell are very refractory galenae, mixed with blende, calamine, pyrites, carbonate of lime, &c., but without any dose of lime. They serve mutually as fluxes to one another. The coal is of inferior quality. The sole of each furnace is formed of slags obtained in the smelting, and they are all of one kind. In constructing it, 7 or 8 tons of these slags are first thrown upon the brick area of the hearth; are made to melt by a brisk fire, and in their stiffening state, as they cool, they permit the bottom to be sloped and hollowed into the desired shape. Four workmen, two at each side of the furnace, perform this task.

The ordinary charge of ore for one smelting operation is 20 cwt., and it is introduced through the hopper. An assistant placed at the back doors spreads it equally over the whole hearth with a rake; the furnace being meanwhile heated only with the declining fire of a preceding operation. No regular fire is made during the first two hours, but a gentle heat merely is kept up by throwing one or two shovelfuls of small coal upon the grate from time to time. All the doors are closed, and the register-plate of the chimney lowered.

The outer basin in front of the furnace is at this time filled with the lead derived from a former process, the metal being covered with slags. A rectangular slu above the tap hole is left open, and remains so during the whole time of the operation, unless the lead should rise in the interior basin above the level of that orifice; in which case a little mound must be raised before it.

The two doors in front furthest from the fire being soon opened, the head-sweeper throws in through them, upon the sole of the furnace, the slags swimming upon the

bath of lead, and a little while afterwards he opens the top-hole, and runs off the molten lead poured from these slags. At the same time he prevents the fire from going out, through the back doors. These being again closed, while the above two first doors are open, the smelter throws a shovelful of small coal or coke under upon the lead bath, and works the whole together, turning over the ore with the paddle or rake. About three quarters of an hour after the commencement of the operation, he throws lime upon the sides of the hearth, the inside slag, which then runs upon the back of the inner basin, and which are mixed with small pieces. He next turns over these slags, as well as the ore with the paddle, and mixes all the mass. At the time the interior bath of the lead only the pig arrives.

The constant new turns over the ore and slag, partly to break the lead apart. A little more than an hour after the operation begins, a quantity of small promising ore is sent into the furnace, is run off by the top, being usually a each quantity as is the half of the inner basin. Each the workmen then turns over the ore, with the paddle, at the several doors of the furnace. Its interior is at this time of a dull red heat, the roasting being carried on rather by the combustion of the coal, than by the heat of the action of the small quantity of lead in the grate. The smelter, after turning the first door with the exception of that next to the grate, lifts off the lead slag lying upon the surface of the inside bath, drains them, and throws them back into the furnace.

An hour and a half after the commencement, the lead begins to run out in small quantities from the ore; but little should be suffered to flow before two hours have expired. About this time the two workmen close all the doors, and turn over the ore, each at his own side of the furnace. An hour and three quarters after the beginning, there are few vapours in the furnace, so temporary being very moderate. No more lead is then seen to flow upon the slating hearth. A general turning over is then made to raise the heat slightly, the workmen turn over the ore, and turn them at the doors.

At the end of two hours, the first fire or roasting being completed, and the lower part, the regulator is to be lifted a little, and coal thrown upon the grate, giving the second fire, which lasts during 25 minutes. When the doors are now opened, the interior of the furnace is of a vivid red colour, and the lead flows down from every side towards the lower basin. The smelter with his rake or paddle pushes the slag upon that back towards the upper part of the ore, and he now spreads them uniformly over the surface through the back doors. The smelter next throws on by his inside door a few shovelfuls of quicklime upon the lead bath. The constant turning over for a quarter of an hour works the ore, and the slag together through the front back doors, and then spreads them out, while the smelter pushes the slag from the surface of the inner basin back to the upper part of the ore. The doors being now left open for a time, while the interior remains in repose, the metallic lead, which had been pushed back with the slag, flows down into the basin. This occasional cooling of the furnace is thought to be necessary for the better separation of the products, especially of the slag from the lead bath.

In a short time the workmen resume their rakes, and turn over the slag along with the ore. Three hours after the commencement, a little more fuel is put into the grate, merely to keep up a moderate heat of the furnace during the pushing. After two hours and ten minutes, the grate being charged with fuel for the third fire, the regulator is completely opened, the doors are all shut, and the furnace is left in this state for three quarters of an hour. In nearly four hours from the commencement, all the doors being opened, the assistant levies the surfaces with his rake, in order to favour the descent of any drops of lead; and then spreads the slag, which are pushed back towards him by the smelter. The latter now throws in a fresh quantity of lime, with the view not merely of covering the lead bath and preventing an oxidation, but of rendering the slag less fluid.

Ten minutes after the third fire is completed, the smelter puts a new charge of fuel on the grate, and shuts the doors of the furnace to give it the fourth fire. In four hours and forty minutes from the commencement, this fire being finished, the doors are opened, the smelter pierces the top-hole to discharge the lead into the outer basin, and throws some quicklime upon the slag in the inner basin. He then pushes the slag thus dried up towards the upper part of the hearth, and his assistant rakes him out by the back doors.

The whole operation of a smelting shift takes about four hours and a half, or at most five hours, in which four periods may be distinguished.

1. The first fire for roasting the ore requires very moderate firing, and lasts two hours.
2. The second fire, or smelting, requires a higher heat, with shut doors; at the end the slag are dried up with lime, and the furnace is also allowed to cool a little.

3. 2. The last two periods, or the third and fourth fires, are likewise the smeltings or soundings, and differ from the first only in requiring a higher temperature. The heat is greatest in the last. The form and dimensions of the furnace are calculated to cause a uniform distribution of heat over the whole surface of the hearth. Sometimes billets of green wood are plunged into the metallic lead of the outer basin, causing an ebullition which favours the separation of the slag, and consequently the production of a purer lead; but no more metallic metal is obtained.

Ten cwt. of coal are consumed at Holywell in smelting one ton of the lead-ore which is or sludge; but at Grassington, near Skipton in Yorkshire, with a similar furnace worked with a slower heat, the operation taking from seven hours to seven hours and a half, instead of five only $7\frac{1}{2}$ cwt. of coal are consumed. But here the ores are less refractory, have the benefit of flint spar as a flux, and are more exhausted of their metal, being smelted upon a less sloping hearth.

The ore-hearth.—This furnace, called by the French *fourneau decousin*, is from 22 to 24 inches in height and 1 foot by $1\frac{1}{2}$ in area inside, but its horizontal section, always rectangular, varies much in its dimensions at different levels, as shown in fig. 1082.

C, Furnace. M, Workstone. P, Lead pot.

Treatment of lead ores by the Scotch furnace or ore-hearth.—This furnace is generally employed in the counties of Northumberland, Cumberland, and Durham, for the smelting of lead ores, which were formerly carried to them without any preparation, but they are now often exposed to a preliminary calcination. The roasted ore yields in the Scotch furnace a more considerable product than the crude ore, because it forms in the furnace a more porous mass, and at the same time it works drier, to use the founder's expression; that is, it allows the stream of air impelled by the blast to diffuse itself more completely across the matters contained in the furnace.

In proceeding to melt by means of an ore-hearth, two workmen are required to be in attendance from the beginning to the end of each smelting shift, the duration of which is from 12 to 13 hours. The first step in commencing a smelting shift is to fill up the hearth-bottom, and space below the workstone with peats, placing one already kindled before the mouth of the bellows. The powerful blast very soon sets the whole in a blaze, and by the addition of small quantities of coal at intervals, a body of fire is obtained, filling the hearth. Roasted ore is now put upon the surface of the fire, between the forestone and pipestone, which immediately becomes heated red hot and reduced; the lead from it sinking down and collecting in the hearth bottom. Other portions of ore of 10 or 12 lbs. each are introduced from time to time, and the contents of the hearth are stirred and kept open, being occasionally drawn out and examined upon the workstone, until the hearth bottom becomes full of lead. The hearth may now be considered in its regular working state, having a mass of heated fuel, mixed with partly fused and semi-reduced ore, called *Brouse*, floating upon a stratum of melted lead. The smelting shift is then regularly proceeded with by the two workmen, as follows:—The fire being made up, a stratum of ore is spread upon the horizontal surface of the brouse, and the whole suffered to remain exposed to the blast for the space of about five minutes. At the end of that time, one man plunges a poker into the fluid lead, in the hearth bottom below the brouse, and raises the whole up, at different places, so as to loosen and open the brouse, and in doing so, to pull a part of it forwards upon the workstone, allowing the recently added ore to sink down into the body of the hearth. The poker is now exchanged for a shovel, with a head 6 inches square, with which the brouse is examined upon the workstone, and any lumps that may have been too much fused, broken to pieces; those which are so far agglutinated by the heat, as to be quite hard, and further known by their brightness, being picked out, and thrown aside, to be afterwards smelted in the slag hearth. They are called "gry slags." A little slaked lime, in powder, is then spread upon the brouse which has been drawn forward upon the workstone, if it exhibit a pasty appearance; and a portion of coal is added to the hearth, if necessary, which the workman knows by experience. In the mean time, his fellow workman, or shoulder fellow, clears the opening, through which the blast passes into the hearth, with a shovel, and places a peat immediately above it, which he holds in its proper situation, until it is fixed, by the return of all the brouse, from the workstone into the hearth. The fire is made up again into the shape before described, a stratum of fresh ore spread upon the part, and the operation of stirring, breaking the lumps upon the

workmen, who, putting on the hard shoes suspended, after the manner of a shoe, exactly in the same manner. At every stirring a fresh part is put above the mass of the bronze, which divides the heat, and causes it to be distributed all over the hearth, and no flame away into light smoke, as happens in the furnace, thus to leave freely into the body of the bronze. The use and purpose of this part renders it very essential for this purpose; but, in some instances, where a tendency of joints has occurred, blocks of wood of the same size have been used with little disadvantage. As the smelting proceeds, the furnace gradually warms, through which it is heated to a proper amount, and brought into use.

The principal particulars to be attended to in smelting or ore-hearth properly during the smelting shift, are three: First—It is very important to maintain a proper blast, which should be carefully regulated, so as to be neither too weak, nor too powerful. The weak blast would cause the furnace to be too hot, and the too powerful has the effect of losing the contents of the hearth too fast. In this particular no certain rules can be given; for the same blast is not equally for every variety of ore. Soft free-grained galena, of great specific gravity, being very fusible, and easily reduced, requires a moderate blast, while the harder and lighter varieties, many of which contain more or less iron, and are often much rich in silver, require a blast considerably stronger. In all cases, it is most essential, that the blast should be so managed as to reduce the ore, after every other necessary precaution is taken in working the hearth. Second—The blast should be as much divided as possible, and made to pass through every part of the bronze. Third—The hearth should be very frequently stirred, at due intervals, and part of its contents exposed upon the workstone; when the part so exposed should be well broken to pieces, as well as those which are further exposed, so as to form slag, carefully packed in. This breaking to pieces, and exposure of the bottom part of the bronze upon the workstone, has a most beneficial effect in promoting the reduction of the lead for the atmosphere, as it is exposed, not only to the air, but also to the heat of the furnace, which is readily consumed, or converted into sulphurous acid, leaving the lead in its metallic state. Hence it is that the reduction of lead is always most abundant out of the hearth immediately after the return of the bronze, which has been exposed and exposed to the atmosphere. Fourth—The quantity of lead used should be no more than is just necessary to keep the bronze sufficiently hot, as it does not in the least contribute to reduce the ore by any chemical effect. Its use is merely to render the bronze too fast, if, from the heat being too great, or from the nature of the ore, it has a disposition to become very soft. Fifth—Coal should be also exposed frequently; too much unnecessarily increasing the bulk of the bronze, and causing the hearth to get too full.

When the ore is of a description to smelt readily, and the hearth is well managed in every particular, it works with but a small quantity of bronze, which feels dry when stirred, and is easily kept open and permeable to the blast. The reduction proceeds rapidly with a moderate degree of heat, and the slag produced are inconsiderable; but, if in this state, the stirring of the bronze and exposure upon the workstone are discontinued, or practised at longer intervals, the hearth quickly gets too hot, and immediately begins to agglutinate together; rendering evident the necessity of these operations to the successful management of the process. It is not difficult to understand why these effects take place, when it is considered, that in smelting by means of the ore-hearth, it is the oxygen of the blast and of the atmosphere which principally accomplishes the reduction; and the point to be chiefly attended to consists in exposing the ore to its action, at the proper temperature, and under the most favourable circumstances. The importance of having the ore free from impurities is also evident, for the stony or earthy matter it contains impedes the smelting process, and increases the quantity of slag. A very slight difference of composition of perfectly dressed ore may readily be understood to affect its reducibility; and hence it is, that ore from different veins, or the same vein in different strata, as before observed, is frequently found to work very differently when smelted singly in the hearth. It happens, therefore, that with the best workmen, some varieties of ore require more coal and heat, and a greater degree of heat than others, and it is for this reason that the foreman is made movable, so as either to answer for ore which, of the with a large or a small quantity of bronze.

It has been stated that the duration of a smelting shift is from 12 to 13 hours, at the end of which time, with every precaution, the hearth is apt to become too hot, and it is necessary to stop for some time, in order that it may cool. At mills where the smelting shift is 12 hours, the hearths usually go on 12 hours, and are suspended 3; four and a half or five blags* of ore (36 to 40 cwt.) are smelted during a shift, and the

two men who manage the hearth work each four shifts per week; terminating their week's work at 3 o'clock on Wednesday afternoon. They are succeeded by two other workmen, who also work four 12-hour shifts, the last of which they finish at 4 o'clock on Saturday. In these eight shifts, from 34 to 40 bings of ore are smelted, which, when of good quality, produce from 9 to 10 fadders* of lead. At other times when the shift is 14 or 15 hours, the furnace is kindled at 4 o'clock in the morning, and worked until 6 or 7 in the evening each day, six days in the week; during this shift, 3 or $3\frac{1}{2}$ bings of ore are smelted, and two men at one hearth, in the early part of each week, work three such shifts, producing about 4 fadders of lead—two other men work each 3 shifts in the latter part of the week, making the total quantity smelted per week, in one hearth, from 30 to 35 bings.

Hearth ends and Smelter's fume.—In the operation of smelting, as already described, it happens that parts of un-reduced and semi-reduced ore are continually expelled from the hearth, partly by the force of the blast, but principally by the disintegration of the ore on the application of heat. This ore is mixed with a portion of the fuel and lime made use of in smelting, all of which are deposited upon the top of the smelting hearth, and are called *hearth-ends*. It is customary to remove the *hearth-ends* from time to time, and deposit them in a convenient place until the end of the year, or some shorter period, when they are washed to get rid of the earthy matter they may contain, and the metallic portion is roasted at a strong heat, until it begins to soften and break into lumps, and afterwards smelted in the ore-hearth, exactly in the same way as the underlying that operation for the first time, as already described.

It is difficult to state what quantity of *hearth-ends* are produced by the smelting of a given quantity of ore, but in one instance the *hearth-ends* produced in smelting 2751 bings, on being roasted and reduced in the ore-hearth, yielded of common lead 315 cwt., and the grey slag separated in this process gave, by treatment in the slag-hearth, 47 cwt. of slag lead; making the total quantity of lead 362 cwt., which is at the rate of 3 cwt. 2 qrs. 23 lbs. from the smelting of 100 bings of ore.

Slag hearth.—The various slags obtained from the different operations of lead smelting are divided into two classes. Those which do not contain a sufficient amount of metal to pay for further treatment are thrown away as useless, whilst those in which the percentage of lead is sufficiently large are treated by the slag-hearth.

Figs. 1093, 1094 represent a slag-hearth, the *furnace à manche* (elbow furnace) of the French, and the *Arummafen* (crooked furnace) of the Germans, each as is used at Alston Moor, in Cumberland, for the reduction of the lead-slag. It resembles the Scotch furnace. The shaft is a parallelopiped, whose base is 26 inches by 24 inches in area inside, and whose height is 3 feet; the sole-plate *a*, of cast iron, slopes slightly

down to the base of reception or the fore-hearth *k*. Upon both of the long sides of the sole-plate there are cast iron beams, called *bauers*, *c c*, of great strength, which support the side walls built of a coarse grained sandstone, as well as the cast iron plate *d* (*fire-stone*), which forms the front of the shaft. This stands 7 inches off from the sole-plate, leaving an empty space between them. The back side is made of cast iron, from the sole-plate to the horizontal tuyère in its middle; but above this point it is made of sandstone. The tuyère is from $1\frac{1}{2}$ to 2 inches in diameter. In front of the fore-hearth *k*, a column *e* is placed, through which water continually flows, so that the slags which spontaneously overflow the fore-hearth may become inflated and divided, whereby the lead disseminated through them may be readily separated by washing. The lead then flows from the fore-hearth *k*, through an orifice, into an iron pot *f*, which is kept over a fire. The metal obtained from this slag-hearth is much less pure than that extracted directly from the ore.

The whole bottom of the furnace is filled to a height of 17 inches, that is, to within 2 or 3 inches of the tuyère, with the rubbish of coke reduced to coarse powder and beat strongly down. At each smelting shift, this bed must be made anew, and the interior of the furnace above the tuyère required, with the exception of the front, consisting of cast iron. In advance of the furnace there is a basin of reception, which is also filled with coke rubbish. Farther off is the pit, full of water, replenished by a cold

* 1 fadder = 28 cwt.

stream, which continually runs in through a pipe. The smoke, which flows out of the furnace, passes over the side, and is the source of ventilation, and does not leave the works, where the smoke-bells, which fly over the furnace, and which they are easily worked, as in the case of the lead that may be extracted during the process.

These furnaces are urged forward by fans or by water wheels, as, fig. 1. But at

the smelting works of Llan-
near Glaston, the blowing-
machine consists of two wheels,
which revolve upon horizontal
axles. Each of these wheels is
divided into two equal parts
by a small plate that passes
through the axle, and is fixed
with water to a certain height.
The water of one side passes
round with that of the other
by an opening in the lower
part of the wheel. Each
wheel produces a movement of

oscillation, produced by a rod attached to a crank of a wheel. At each stroke, one of the compartments, being in communication with the external air, is filled, whilst the other, on the contrary, communicates with the furnace, and supplies
fuel to the furnace.

Instead of being blown by a cold blast, these furnaces are sometimes supplied with heated air. When supplied with cold air, it is often found difficult to penetrate the quantity of slag or other substance, so as to produce the necessary heat, and the cost of slag which forms at the end of the furnace from the cold blast, is the property of the operation. When the substance operated on is pure for silver, and very valuable, it frequently happens that the smelter is obliged to break the same, or to add some very fusible substance in order to melt it off. By the introduction of hot air the inconvenience is removed, and by increasing or lowering the temperature of the blast, the slag may be allowed to lengthen or shorten, according as the nature of the slag may require. The temperature found to answer best is from 200° to 250° Fahr.; and when it is heated to from 200° to 250°, it is found impossible to form a slag of sufficient length to convey the blast to the front of the hearth, and therefore the back, which is expensive to rebuild, is quickly destroyed.

The advantage to be derived from the use of the hot blast will be evident, from the result of two experiments which were tried some years since.

Twenty-eight tons of slag smelted with cold blast consumed 372 cubic feet of air per minute.

Labour cost - - - - -	£3 7 8
Coke, 7 tons, at 24s. 6d. - - - - -	8 11 6
Total	£11 19 2

Thirty-five tons of similar slag smelted with hot blast consumed 300 cubic feet of air per minute.

Labour cost - - - - -	£3 7 8
Coke, 3 tons, 17 cwt., at 24s. 6d. - - - - -	7 8 4
Turf for heating air, 11 loads, 1s. 8d. - - - - -	0 10 4
Total	£11 9 4

From which it will be seen that, with one-quarter part less air, a quarter part more slag was melted per week, and a saving of expense of nearly 10s. effected.

The loss of lead experienced in smelting by the slag hearth, is, however, very great, even under the most favourable circumstances; and it has, consequently, of late years been gradually superseded by the Castilian furnace, which will be shortly described. Many large and well-conducted establishments still, however, continue to employ the slag hearth, and when well constructed and skilfully managed, the loss arising from volatilisation may be considerably reduced.

Castilian furnace — Within the last few years a blast furnace has been introduced into the lead works of this country, which possesses great advantages over every other description of apparatus which has been hitherto employed for the treatment of lead ore of low produce. This apparatus, although first employed in Spain, was invented by an Englishman (Mr. W. Grundy), who was employed in the reduction of rich slags in the neighbourhood of Carthagena.

This furnace is circular, usually about 2 feet 4 inches, or 2 feet 6 inches in

diameter, and is constructed of the best fire bricks, so moulded as to fit together, and allow all the joints to follow the radii of the circle described by the brick work. Its usual height is 8 feet 6 inches, and the thickness of the masonry invariably 8 inches. In this arrangement the breast is formed by a semi-circular plan of cast-iron, furnished with a lip for running off the slag, and has a longitudinal slot, in which is placed the tapping-hole.

On the top of this cylinder of brickwork a box-shaped covering of masonry is supported by a cast-iron framing, resting on four pillars, and in this is placed the door for feeding the furnace, and two outlets by which the various products of combustion escape to the flues. The lower part of this hood is fitted closely to the body of the furnace, whilst its top is closed by an arch of 4½ inch brickwork laid in fire-clay. The bottom is composed of a mixture of coke-dust and fire-clay, slightly rammed, and well beaten to the height of the top of the breast-pan, which stands nearly 3 feet above the level of the floor. Above the breast-pan is an arch, so turned as to form a sort of niche, 18 inches in width, and rather more than 2 feet in height.

When the bottom has been solidly beaten, up to the required height, it is hollowed out so as to form an internal cavity, communicating freely with the breast-pan, which is filled with the same material and subsequently hollowed out to a depth exactly below the level of the internal cavity. The blast is supplied by three water tuyeres, 3 inches in diameter at the smaller end, 5½ inches at the larger, and 10 inches in length. Into these the nozzles are introduced, by which a current of air is supplied by means of a fan or ventilator, making about 100 revolutions per minute. The blast may be conveniently conducted to the nozzles through brick channels formed beneath the floor of the smelting house.

The ores treated in this furnace ought never to contain more than 30 per cent. of metal, and when richer, must be reduced to about this tenure by the addition of slags and other fluxes. In charging this apparatus, the coke and ore are supplied stratum super stratum, and care must be taken so to dispose the coke as not to heat too violently the brickwork of the furnaces. In order to allow the slags which are produced to escape freely into the breast-pan, a brick is lifted out of the front of the furnace at the height of the fire-hearth, which, for the purpose of preventing the cooling of the section, is kept covered by a layer of coke-dust or cinders. From the breast-pan the slag flows constantly off over a spout into cast-iron waggonets, where they consolidate into masses, having the form of truncated pyramids, of which the larger base is about 2 feet square. As soon as a sufficient amount of lead is accumulated in the bottom of the furnace, it is let off into a lateral lead-pot, by removing the clay-stopper of the tap-hole situated in the side of the breast-pan, and after being properly skimmed it is ladled into moulds. When in addition to lead the ore treated likewise contains a certain portion of copper, this metal will be found in the form of a matt floating on the surface of the leaden bath. This, when partially solidified, is removed, and after being roasted is operated on for the copper it contains.

The waggonets in which the liquid slag runs off, are frequently made to traverse small railways, by which, when one mass has been removed, its place may readily be supplied by an empty wagonnet. When nearly cold the casings of the wagonets are turned over and the blocks of slag easily made to drop out. In addition to the facility for transport obtained in this way, one of the great advantages obtained by this method of manipulation arises from the circumstance that should the furnaces at any time run lead or matt, without its being detected by the smelter, the whole of it will be collected at the bottom of the block, from which, when cold, it may be readily detached.

In working these furnaces, care must be taken to prevent flame from appearing at the tunnel-head, since, provided the slags are sufficiently liquid, the cooler the apparatus is kept the less will be the loss of metal through volatilisation. In addition to the greatest attention being paid to the working of the furnace, it is necessary, in order to obtain the best results, that all establishments in which this apparatus is employed should be provided with long and capacious flues, in which the condensation of the fumes takes place, previous to arriving at the chimney-shaft. These flues should be built at least three feet in width, and six feet in height, so as readily to admit of being cleaned, and are often made of several thousand yards in length. The value of the fumes, so condensed, amounts to many hundreds, and in some instances thousands per annum.

In order to be advantageously worked in these furnaces, the ores should be first roasted, and subsequently agglomerated into masses, which, after being broken into fragments, of about the size of the fist, and mixed with the various fluxes, are charged as before described.

In an establishment in which the average assay produce of the roasted ore for lead

is 42 lbs, the furnace yield is 44 lbs, and the weight of coke employed to effect the reduction 22 per cent. of the roasted ore operated on. The mixture charged into the furnace, in this instance, is composed of 100 parts of roasted ore, 42 parts of coke from a previous operation, 5 parts of scrap iron, and 7 parts of limestone. Each furnace works off about seven tons of roasted ore in the course of 24 hours; the weight of slag run off is about double that of the lead obtained, and the matt removed from the surface of the pan is nearly 3 per cent. of the lead produced. The ores treated in this establishment consist of galena, much mixed with spathose iron, and are therefore somewhat refractory. A furnace of this kind requires for its construction about 1000 segmental fire-bricks, and the same number of ordinary fire-bricks of second quality.

Figs. 1086, 1087, 1088, and 1089 represent respectively a vertical section, an elevation, a ground plan, and an horizontal section of a Castilian furnace. The section fig 1086 is on the line x v. fig. 1087. A is the body of the furnace; n, the bottom composed of a mixture of lime-dust and fire-clay; c c c, the layers; r, the rectangular covering of masonry; k k k, cast iron pillars; v, the breast-pan; a, slot for tapping hole; n, lip of breast-pan; z, feeding door; u, fire-hole; r. q. ground line.

Figs. 1090, 1091 are the slag-waggons, A being a movable case without a bottom, and B a strong cast-iron plate running on four wheels.

The desulphuration of the ores to be treated in these furnaces may be effected either by the aid of an ordinary reverberatory roasting furnace, or in heaps, or properly constructed kilns.

The kilns best adapted for this purpose consist of rectangular chambers, having an arched roof, and provided with proper flues for the escape of the evolved gases, as well as a wide door for charging and withdrawing the ore to be operated on.

Each of these chambers is capable of containing from 25 to 30 tons of ore, and in order to charge it a layer of faggots and split wood is laid on the floor, and then, after having been covered by a layer of ore about two feet in thickness, is ignited, care being at the same time taken to close, by means of loose brick-work, the opening of the door to the same height. When this first layer has become sufficiently ignited, a fresh stratum of ore, mixed with a little coal or charcoal, is thrown upon it, and when this layer has in its turn become sufficiently heated, more ore is thrown on. In this way more ore is from time to time added, until the kiln has become full, when the orifice of the doorway is closed by an iron plate, and the operation proceeds regularly and without further trouble until the greater portion has become eliminated.

This usually happens at the expiration of about four weeks from the time of first ignition, and the brick-work front is then removed, and the ores broken out, and after being mixed with proper fluxes, passed through the blast furnace.

The proportion of wood necessary for the roasting of a ton of ore by this means must necessarily depend on the composition of the minerals operated on; but with ores of the description above-mentioned, and in a neighbourhood where wood is moderately cheap, the desulphuration may be effected at a cost of about 5s. per ton.

Calining.—The lead obtained by the various processes above described generally contains a sufficient amount of silver to render its extraction of much importance; but, in addition to this, it is not unfrequently associated with antimony, tin, copper, and various other impurities, which require to be removed before the separation of the silver can be effected.

This operation consists in fusing the hard lead in a reverberatory furnace of peculiar construction and allowing it to remain, when in a melted state, exposed to the oxidizing influences of the gases passing through the apparatus. By this treatment the antimony, copper, and other impurities become oxidised, and on rising to the surface of the molten bath are skimmed off, and removed with an iron rake. The hearth of the furnace in which this operation is conducted consists of a large cast-iron pan, which may be 10 feet in length, 5 feet 6 inches in width, and 10 inches in depth. The fire-place, which is 1 foot 9 inches in width, has a length equal to the width of the pan, and is separated from it by a fire-bridge 2 feet in width. The height of the arch at the bridge end is 1 foot 4 inches above the edge of the pan, whilst at the outer extremity it is only about 4 inches.

The lead to be introduced into the pan is first fused in a large iron pot fixed in
r v 3

be h-work at the side of the furnace, and subsequently ladled into it through an iron gutter adapted for that purpose. The length of time necessary for the purification of hard lead obviously depends on the nature and amount of the impurities which it contains; and, consequently, some varieties will be sufficiently refined at the expiration of twelve hours, whilst in other instances it is necessary to continue the operation during three or four weeks. The charge of hard lead varies from eight to eleven tons.

When the metal is thought to be in a fit state for tapping, a small portion taken out with a ladle, and poured into a mould used for this purpose is found on cooling to assume at the surface a peculiar crystalline appearance, which, when more seen is readily again recognised. As soon as this appearance presents itself an iron plug is withdrawn from the bottom of the pan, and the lead ran off into an iron pan, from which it is subsequently ladled into malle.

The items of cost attending the calcining of one ton of hard Spanish lead in the north of England are about as follows:—

	a.	d.
Wages	1	11 7
Onals, 27 cwt	0	4 7
It-pans, &c.	0	0 5
	<hr/>	
	2	4 4

The construction of a furnace of this description requires 5000 common bricks, 3,500 fire-bricks, and 2 tons of fire clay.

Figs. 1092 and 1093 represent an elevation and vertical section of the calcining

furnace. A is the fire-place; N, ash-pit; C, fire-bridge; H, cast iron pan; Z, fire; F F F, channels for allowing the escape of moisture; H, one of the working doors. H, apart for

running off calcined metal. Fig. 1094 represents the pan removed from the masonry, and shows a groove in the lip for the introduction of a sheet iron dam, tightened with malle and bone-ash for keeping in the fused metal.

In the more modern furnaces of this description, the corners are usually rounded to prevent breakage from expansion, whilst the tapping is effected by means of a hole through the bottom near one of the sides. This, when closed, is stopped by means of an iron plug kept in its place by a weighted lever.

Concentration of the silver.—This process is founded on the circumstance first noticed in the year 1729, by the late H. L. Pattinson of Newcastle-on-Tyne, that

when lead containing silver is melted in a suitable vessel, afterwards slowly allowed to cool, and at the same time kept constantly stirred, at a certain temperature near the melting point of lead, metallic crystals begin to form. These as rapidly as they are produced sink to the bottom, and on being removed are found to contain much less silver than the lead originally operated on. The still fluid portion, from which the crystals have been removed, will at the same time be proportionally enriched.

This operation is conducted in a series of 4 or 5 cast iron pots, set in a row, with fireplaces beneath. These are each capable of containing about 4 tons of calcined lead; and on commencing an operation that quantity of metal, containing we will suppose 20 oz. of silver per ton, is introduced into a pot (say *r*, fig. 1095) about the centre of the series. This when melted, is carefully skimmed with a perforated ladle, and the fire immediately withdrawn. The cooling of the metal is also frequently hastened by throwing water upon its surface, and whilst cooling it is kept constantly agitated by means of a long iron stirrer or *stirrer*. Crystals soon begin to make their appearance, and these as they accumulate and fall to the bottom are removed by means of a large perforated ladle, in which they are well shaken and afterwards carried over to the next pot to the left of the workman. This operation goes on continually until about 4 tons of crystals have been taken out of the pot *r*, and have been placed in pot *x*, at which time the pot *r*, may contain about 40 oz. of silver to the ton, whilst that in *x*, will only yield 10 oz. The rich lead in *r*, is then ladled into the next pot *u*, to the right of the workman, and the operation repeated in *r*, on a fresh quantity of calcined lead.

In this way calcined lead is constantly introduced, and the resulting poor lead passes continually to the left of the workman, whilst the rich is passing towards his right. Each pot in succession, when filled with lead of its proper produce for silver, is in its turn crystallised, the poor lead passing to the left of the workman, and the enriched lead to his right. By this method of treatment it is evident that the crystals obtained from the pots to the left of the workman must gradually be deprived of their silver, whilst the rich lead passing to his right becomes continually richer. The final result is, that at one end of the series, the poor lead contains very little silver, whilst at the other an exceedingly rich alloy of lead and silver is obtained.

The poor lead obtained by this process should never contain more than 12 dwts. of silver per ton, whilst the rich lead is frequently concentrated to 500 oz. to the ton. This rich lead is subsequently expelled in the refining furnace.

The ladle employed for the removal of the crystals, when manual labor is used, is about 16 inches in diameter, and 3 inches in depth, but when cranes are used much larger ladles are usually employed. A form of crane has been invented which effects considerable economy of labor in this operation. When, during the operation of crystallization, the ladle becomes chilled, it is dipped into a small vessel containing lead of a higher temperature than that which is being worked, and drawn by the means of a snapper-pot. The pot containing the rich lead is generally used like No. 1 pot; in some establishments, however, the last pot is when the poor lead or crystal lead obtains this application.

Figs. 1095 and 1096 represent a plan and elevation of a set of Pattinson's pots, arranged in the usual approved way. A is the "market pot," from which the de-silvered lead is ladled out. B, C, D, E, F, G, H, and I, are the working pots, while A', B', C', D', E', F', G', H', and I, are their respective fireplaces. The "snapper pots" W, X, Y, Z, are employed for heating the ladles when they have become too much reduced in temperature.

The Figs. 1097 and 1098, are sections showing the manner of setting and the arrangement of the pots and flues. A, pot; B, main flue; C, ash pit.

1097

1098

The cost of crystallizing one ton of calcined Spanish lead, in the establishments quoted when treating of calcination, is as follows:—

	s.	d.
Wages	9	5.4
Coals, 4 cwt.	0	8.8
Repairs	0	2.5
Total	10	4.2

The erection of nine six-ton pots requires 15,000 common bricks, 10,000 fire bricks, 160 feet of quartz, 80 fire-clay blocks, and 3 tons of fire-clay.

In some establishments ten-ton pots are employed, and where cranes are made use of they are found to be advantageous.

Refining.—The extraction of the silver contained in the rich lead is conducted in a cupel forming the bottom of a reverberatory furnace called a refinery.

In this operation the litharge produced, instead of being absorbed by the substance of the cupel, is run off in a fluid state, by means of a depression called a gate.

The size of the fire-place varies with the other dimensions of the furnace, but is usually nearly square, and is an apparatus of ordinary size may be about 2 feet x 2 feet 6 inches. This is separated from the body of the furnace by a fire-bridge 18 inches in breadth, so that the flame and heated air pass directly over the surface of the cupel, and from thence escape by means of two separate apertures into the main flues of the establishment. The cupel or test consists of an oval iron ring, about 5 inches in depth, its greatest diameter being 4 feet, and its lower nearly 3 feet. This frame, in order to better support the bottom of the cupel, is provided with cross-bars about 4½ inches wide, and one half-inch in thickness. In order to make a test, this frame is beaten full of finely-powdered bone-ash, slightly moistened with water, containing a small quantity of pearl-ash in solution, which has the property of giving consistency to the cupel when heated.

The centre of the test, after the ring has been well filled with this mixture, and solidly beaten down, is scooped out with a small trowel, until the sides are left 2 inches in thickness at top, and three inches at the bottom, whilst the thickness of the sole itself is about 1 inch.

At the fore part or wide end of the test the thickness of the border is increased to six inches, and a hole is then cut through the bottom, which communicates with the openings or gates by which the fluid litharge makes its escape.

The test, when thus prepared, is placed in the refinery furnace, of which it forms the bottom, and is wedged to its proper height against an iron ring firmly built into the masonry. When this furnace is first lighted, it is necessary to apply the heat very gradually, since if the test were too strongly heated before it became perfectly dry, it would be liable to crack. As soon as the test has become thoroughly dry, it is heated to incipient redness, and is nearly filled with the rich lead to be operated on, which has been previously fused in an iron pot at the side of the furnace, and beneath which is a small grate where a fire is lighted.

The melted lead, when first introduced into the furnace, becomes covered with a greyish dross, but on further increasing the heat, the surface of the bath uncovers, and ordinary litharge begins to make its appearance.

The blast is now turned on, and forces the litharge from the back of the test up to the breast, where it passes over the gate, and falls through the aperture between the bone-ash and the ring into a small cast-iron pot running on wheels. The air, which is supplied by a small ventilator, not only sweeps the litharge from the surface of the lead towards the breast, but also supplies the oxygen necessary for its formation.

In proportion as the surface of the lead becomes depressed by its constant oxidation, and the continual removal of the resulting litharge, new metal is added from the melting pot, so as to raise it to its former level, and in this manner the operation is continued until the lead in the bottom of the test has become so enriched as to render it necessary that it should be tapped. The contents of the test are now so far reduced in volume that the whole of the silver contained in the rich lead operated on remains in combination with a few hundred weight only of metal, and this is removed by carefully driving a hole in the bone-ash forming the bottom of the test. The reason for the removal of the rich lead, is to prevent too large an amount of silver from being carried off in the litharge, which is found to be the case when lead containing a very large amount of that metal is operated on.

When the rich lead has been thus removed, the tapping hole is again closed by a pellet of bone-ash, and another charge immediately introduced.

As soon as the whole of the rich lead has been subjected to cupellation, and has become thus further enriched, the argentiferous alloy is itself similarly treated, either in a fresh test, or in that employed for the concentration of the rich lead. The brightening of pure silver at the moment of the separation of the last traces of lead, indicates the precise period at which the operation should be terminated, and the blast is then turned off, and the fire removed from the grate. The silver is now allowed to set, and as soon as it has become hardened, the wedges are removed from beneath the test, which is placed on the floor of the establishment. When cold, the silver plate is detached from the test, and any adhering particles of bone-ash removed by the aid of a wire brush.

A test furnace of ordinary dimensions requires for its construction about 2,000 common bricks, 2,000 fire-bricks, and 1½ tons of fire-clay. A furnace of this kind will work off 4 tons of lead per hour, and consumes 4 cwt. of coal per ton of rich lead operated on.

The cost of working a ton of rich lead in the neighbourhood of Newcastle, containing on an average 400 oz. of silver per ton, is as follows:—

Figs. 1099, 1100, and 1101, represent an elevation, plan, and section of a refining furnace; a, fireplace; n, ash-pit; c, fire-bridge; d, water-ring, shown in its proper position; e, flues; f, point where blast enters; g, pig-holes.

* Pig-bins are used for intr. during the test in cases in which it is not loaded. The test is a fixed at 30.

Reducing.—The reduction to the metallic state of the litharge from the refinery, the pot dross, and the metal contained within the melting furnace, is effected in a reverberatory apparatus, somewhat resembling a smelting furnace, except that its dimensions are smaller, and the bed, instead of being lower, is usually below the middle of the furnace, gradually sloping from the fire-bricks to water the flue, where there is a depression in which is located an iron gutter, which constantly remains open, and from which the reduced metal flows continuously into an iron pot placed by the side of the furnace for its reception, whence it is subsequently ladled into moulds.

The litharge, or pot dross, is intimately mixed with a quantity of small coal, and is charged on the part of the hearth immediately before the fire-bridge. To prevent the fuel from striking the bottom of the furnace, and also to provide a sort of hollow filter for the liquid metal, the sole is covered by a layer of bone-ash.

The heat of the furnace quickly causes the ignition of this stratum, which is rapidly reduced to the state of a spongy cinder. The reducing gases present in the furnace, aided by the coal mixed with the charge itself, cause the reduction of the metal, which, passing the metal in form, flows through the interstices of the cinder, and ultimately finding its way into the depression at the extremity of the hearth, flows through the iron gutter into the external cast-iron pot. The surface of the charge is frequently, during the process of elaboration, turned over with an iron rake, for the double purpose of exposing new surface to the action of the furnace, and also to allow the reduced lead to flow off more readily.

Fresh quantities of litharge or pot-dross, with small coal, are from time to time thrown in, in proportion as that a ready supply disappears, and at the end of the shift, which usually extends over 12 hours, the layer of cinder is broken up, and after being mixed with the residual material in the furnace is withdrawn. A new floor of cinders is then introduced, and the operation commenced as before. A furnace of this kind, having a sole 6 feet in length and 7 feet in width, will afford, from litharge, about $3\frac{1}{2}$ tons of lead in 24 hours.

The dross from the calcining pan, when treated in a furnace of this description, should be previously reduced to a state of fine division, and intimately mixed up with small coal and a soda ash. In many cases, however, the calcined dross is treated in the smelting furnace. The hard lead obtained from this substance is again taken to the reducing furnace, for the purpose of being softened.

The expense of reducing one ton of litharge may be estimated as follows —

	s.	d.
Wages	2	6.0
Coals (3 cwt.)	0	5.2
Repairs	0	1.6
Total	3	0.8

In the establishment from which the foregoing data were obtained, the cost of slack, delivered at the works, was only 2s. 11d. per ton, which is cheaper than fuel can be obtained in the majority of the lead-mills of this country. In North Wales the cost of small coal is generally about 4s., and at Bristol 5s. 6d. per ton.

1102

Figs. 1102 and 1103 represent a vertical section and plan of a reducing furnace. A, fire-place; u, ash-pit; c, fire-bridge; b, hearth; r, working door; z, iron spout for

conducting the reduced metal into the lead-pot *d*, which is kept heated by means of a fire beneath.

The total cost of elaborating one ton of hard lead, containing 30 oz. of silver per ton, in a locality in which fuel is obtained at the low price above quoted, is nearly as follows:—

	£	s.	d.
Calcining	0	2	4½
Crystallising	0	9	6½
Refining	0	0	9½
Refining—put dross and litharge	0	1	0½
Calcined dross	0	0	8½
Slags	0	6	3½
Booze-nash, &c.	0	0	7½
Transport, &c.	0	1	1½
Management, taxes, and interest of plant	0	5	10½
Total	1	2	5½

One hundred tons of hard lead treated gave:—

	Tons
Soft lead	94.90
Black dross	3.72
Loss	1.38
Total	100.00

On comparing the expense of each operation, as given in the foregoing abstract, with the amounts stated as the cost of each separate process, they will be found to be widely different; but it must be remembered that the whole of the substances elaborated are far from being subjected to the various treatments described.

In order therefore to give an idea of the relative proportions which are passed through the several departments, I may state that in an establishment in which the ores are treated in the Castilian furnace the following were the results obtained:—

One-hundred parts of raw ore yield:—

Roasted ore	85
Hard lead	42
Soft	36
Rich	9
Dross and litharge re-treated	18½

The importance of this branch of our metallurgic industry will be gathered from the following tabular statements, chiefly derived from Mr. Hunt's valuable statistics:—

TABLE I.

It may be remarked that for the treatment of ores of good produce the reverberatory furnace and Scotch hearth are to be preferred, but for working minerals of a low percentage the blast furnace may generally be substituted with advantage. The slag hearth, from the amount of fuel consumed and loss experienced, is a somewhat expensive apparatus, and might in many cases be advantageously exchanged for the Castilian furnace.

It is well known that the losses which take place in this branch of metallurgy are,

from the volatility of the metal operated on, usually, large. In those cases, however, in which the attention is paid to safety and a proper adjustment of ore, as well as the reduction of the expense, a great economy is effected.

In some instances fluxes of three, five, or even in some cases ten, have been employed, and the most satisfactory results obtained. The attention of lead smelters is being daily more directed to the prevention of the loss of metal by volatilization, and those who have adopted the use of long flues have been, in all cases, quickly repaid for their outlay.

As an example of the great extent to which such economy may take place on the small employed in large smelting works, we may mention the lead works belonging to Mr. Henson at the Northampton. Formerly the fumes of lead arising from various smelting operations escaped from ordinary chimneys or short flues, and large quantities of lead were thus carried off to the waste of vapour, and deposited in the surrounding land, where vegetation would be destroyed, and the health of both man and other animals seriously affected. This led to various estimations of the loss of metal or slightly inclined galleries were in use, and the quantity of lead extracted rapidly repaid the cost of construction. The last alteration of the kind was made at Allen Mill, by Mr. Spewth, the manager, and comprised a length of 275 yards (nearly five miles) of long gallery from the mill itself. This gallery is 4 feet high and 16 wide, and is two distances widely separated. There are two rows of chimneys of galley for the same purpose, running with other mines belonging to Mr. Henson in the same district, and in Durham, and we learn from Mr. Spewth, that former estimations are completely exceeded. The value of the lead thus saved from being totally dissipated and destroyed, and obtained from what in common parlance might be called chimney sweeps, is considerably exalted to 1000*l.* sterling annually, and forms a striking illustration of the importance of economy in our waste products.

In the use of long and extensive flues, chimneys of various descriptions have from time to time been introduced, but in most instances the former have been found to be more efficient.

When, however, water can be procured for the purpose of heating the chimneys, excellent results are generally obtained.—J. A. P.

See LITHUANIAN, MINERAL, or Red Lead, BOLLIN, STUAM or Arslate of LEAD, TERN, METAL, and WHITE LEAD.

LEAD ORES, ASSAY OF. The uses of lead may be divided into two classes.

The first class comprehends all the ores of lead which contain neither sulphur nor arsenic, or in which they are present in small proportion only.

The second class comprises galena, together with all lead ores containing sulphur, arsenic, or their acids.

From the facility with which this metal is volatilized when strongly heated, it is necessary to conduct the assay of its ores at a moderate temperature.

A common wind furnace is best adapted for making lead assays. For this purpose the cavity for the reception of fuel should be 2 inches square, and the height of the flue-way from the fire-bars about 14 inches. For ordinary ores a furnace 8 inches square and 12 inches deep will be found sufficient; but as it is easy to regulate, by a damper, the heat of the larger apparatus, it is often found advantageous to be able to produce a high temperature.

A furnace of this kind should be connected with a chimney of at least twenty feet in height, and be supplied with good coke, broken into pieces of the size of eggs.

ORES OF THE FIRST CLASS.—The assay of ores of this class is a simple operation, care being only required that a sufficient amount of carbonaceous matter be added to effect the reduction of the metal, whilst such fluxes are supplied as will afford a readily-fusible slag.

When the sample has been properly reduced in size, 400 grains are weighed out and well mixed with 600 grains of carbonate of soda, and from 40 to 50 grains of finely-powdered charcoal, according to the richness of the mineral operated on.

This is introduced into an earthen crucible, of such a size as not to be more than one-half filled by the mixture, and on the top is placed a thin layer of common salt. The crucible is then placed in the furnace and gently heated, care being taken to so moderate the temperature, that the mixture of ore and flux, which at first begins to soften and enter into ebullition, may not swell up and flow over. If the action in the crucible becomes too strong, it must be checked by removal from the fire, or by a due regulation of the heat by means of a damper. When the action has subsided, the temperature is again raised for a few minutes, and the assay completed. During the process of reduction, the heat should not exceed dull redness; but in order to complete the operation, and render the slag sufficiently liquid, the temperature should be raised to bright redness.

When the contents have been reduced to a state of tranquil fusion, the crucible must be removed from the fire and the assay either rapidly poured, or, after being tapped against some hard body to collect the lead in a single globule, be set to cool.

When the operation has been successfully conducted, the cooled slag will present a smooth, convex surface, with a various lustre. When still the crucible may be broken, and the button extracted. To remove from it the particles of adhering slag, it is hammered on an anvil, and afterwards rubbed with a lead brush.

Instead of employing carbonate of soda and powdered charcoal, the ore may be fused with $1\frac{1}{2}$ times its weight of black flux, and the mixture covered by a thin layer of borax.

Good results are also obtained by mixing together 400 grains of ore with an equal weight of carbonate of soda and half that quantity of crude tartar. These ingredients, after being well incorporated, are placed in a crucible, and slightly covered by a layer of borax.

Each of the foregoing methods yields good results, and affords slags retaining but a small proportion of lead.

Ores of the Spanish Class.—This class comprehends galena, which is the most common and valuable ore of lead, and also comprises several smaller products, as well as the sulphate, phosphate, and arsenate of lead.

Galena.—The assay of this ore is variously conducted; but one of the following methods is usually employed for commercial purposes.

Fusion with an alkali flux.—This operation is conducted in an earthen crucible which is to be kept covered until the contents are reduced to a state of perfect fusion.

The powdered ore, after being mixed with three times its weight of carbonate of soda and 10 per cent. of finely pulverized charcoal, is slowly heated in an ordinary assay furnace, and the mixture has become perfectly liquid, when the pot is removed from the fire, and, after having been gently tapped, to collect any loose particles of metal held in suspension in the slag, is put back to cool. When sufficiently cold, the crucible is broken, and a button of metal—lead will be found at the bottom; this must be cleaned and weighed.

In place of carbonate of soda, pearl ash may be employed, or the fusion may be effected with black flux alone. When the last-named substance is used a somewhat longer time is necessary for the complete fusion of the assay. Each 100 parts of pure galena will by this method afford from 74 to 76 parts of lead.

Some of the old assays were in the habit of first driving off the sulphur by roasting, and afterwards fusing the resulting oxide with about its own weight of black flux.

This method, from the great instability of the compounds of lead, requires very careful management, and at best the results obtained are unsatisfactory. Pure galena by this method can rarely be made to yield more than 70 per cent. of lead.

Fusion with metallic iron.—Mix the ore to be assayed with twice its weight of carbonate of soda, and, after having placed it in an earthen crucible, of which it should occupy about one half the capacity, insert with their heads downward three or four tempering nails, and press the mixture firmly around them. On the top place a thin layer of borax, which should be again covered with a little common salt. The whole is now introduced into the furnace, and gradually heated to redness; at the expiration of ten minutes the temperature is increased to bright redness, when the fluxes will be fused and present a perfectly smooth surface. When this has taken place, the pot is removed from the fire, and the nails are separately withdrawn by the use of a small pair of tongs, care being taken to well cleanse each in the fluid slag until free from adhering lead. When the nails have been thus removed, the pot is gently shaken, to collect the metal into one button, and laid aside to cool; after which it may be broken, and the button removed.

Instead of first allowing the slags to cool and then breaking the crucible, the assay may, if preferred, after the withdrawal of the nails, be poured into a mould.

Assay in an iron pot.—Instead of adding metallic iron to the mixture of ore and flux, it is generally better that the pot itself should be made of that metal.

For this purpose, a piece of half-inch plate-iron is turned up in the form of a crucible and carefully welded at the edges. The bottom is closed by a thick iron rivet, which is securely welded to the sides, and the whole then finished on a properly formed mandril. To make an assay in a crucible of this kind, it is first heated to dull redness, and, when sufficiently hot, the powdered ore, intimately mixed with its own weight of carbonate of soda, half its weight of pearl ash, and a quarter of its weight of crude tartar, is introduced by means of a copper scoop. On the top of the whole is placed a thin layer of borax, whilst the crucible, which, for the ready introduction of the mixture, has been removed from the fire, is at once replaced. The heat is now raised to redness, the contents gradually becoming liquid and giving off large quantities of gas. At the expiration of from eight to ten minutes the mixture will be in a state of complete fusion; the pot is now partially removed from the fire, and its contents briskly stirred with a small iron rod. Any matter adhering to its sides is also scraped to the bottom of the pot, which, after being again placed in a hot part of the furnace, is heated during three or four minutes to bright redness.

LEAD-SHOT. (*Pom de Chasse, Fr.; Schrot, Pöschel, Ger.*) The origin of some of the imperfections in the manufacture of lead shot is the too rapid melting of the spherules by their being dropped too soon into the water, whereby their surfaces form a hard crust, while the interior remains fluid, and in its subsequent coagulation, shrinks, so as to produce the irregularities of the shot.

The poorest shot towers originally constructed in England abate this evil by exposing the fused spherules after they pass through the cullender, to a large body of water during their descent into the water tub placed on the ground. The highest erection of this kind is probably at Völsch in Carinthia, being 240 Vienna, or 245 English feet high.

The quantity of arsenic added to the mass of melted lead varies according to the quality of the metal; the harder and less ductile the lead is, the more arsenic must be added. About 3 pounds of either white arsenic or arsenic is enough for one thousand parts of soft lead, and about 4 for the harder kinds. The latter are employed generally for shot, as they are cheaper and answer sufficiently well. The arsenical alloy is made either by introducing some of this substance at each melting, or by making a quantity of the compound considerably stronger at once, and adding a certain portion of this to each charge of lead. If the particles of the shot appear less shaped, it is a proof that the proportion of arsenic has been too great; but if they are flattened upon one side, if they are hollowed in their middle, called *cupping* by the workmen, or drag with a tail behind them, the proportion of arsenic is too small.

The following is the process prescribed by the patentees, A. Kerman and Martin. Melt a ton of soft lead, and sprinkle round its sides in the iron pot about two shovelfuls of wood ashes, taking care to leave the centre clear; then put into the middle about 40 pounds of arsenic to form a rich alloy with the lead. Cover the pot with an iron lid, and lute the joints quickly with loam or mortar to confine the arsenical vapours, keeping up a moderate fire to maintain the mixture fluid for three or four hours; after which skim carefully, and run the alloy into moulds to form ingots or pigs. The composition thus made is to be put in the proportion of one pig or ingot into 1000 pounds of melted ordinary lead. When the whole is well combined, take a perforated skimmer, and let a few drops of it fall from some height into a tub of water. If they do not appear globular, some more arsenical alloy must be added.

Lead which contains a good deal of pewter or tin must be rejected, because it tends to produce elongated drops or tails.

From two to three tons are usually melted at once in the large establishments. The surface of the lead gets covered with a crust of oxide of a white spongy nature, sometimes called *crum* by the workmen, which is of use to coat over the bottom of the cullender, because without such a bed the heavy melted lead would run too rapidly through the holes for the granulating process, and would form oblong spheroids. The mounting of this filter, or lining of the cullender, is reckoned to be a nice operation by the workmen, and is regarded usually as a valuable secret.

The cullenders are hollow hemispheres of sheet iron, about 10 inches in diameter, perforated with holes, which should be perfectly round and free from burr. There must be of an uniform size in each cullender; but of course a series of different cullenders with sorted holes for every different size of lead shot must be prepared. The holes have nearly the following diameters for the annexed numbers of shot.

No.	0.	1.	2.	3.	4.	$\frac{1}{20}$ of an inch.
	-	-	-	-	-	$\frac{1}{16}$ "
	-	-	-	-	-	$\frac{1}{8}$ "
	-	-	-	-	-	$\frac{3}{16}$ "
	-	-	-	-	-	$\frac{1}{2}$ "
	-	-	-	-	-	$\frac{3}{4}$ "

From No. 5. to No. 9. the diameter decreases by regular gradations, the latter being only $\frac{1}{16}$ of an inch.

The operation is always carried on with three cullenders at a time; which are supported upon projecting grates of a kind of chafing dish made of sheet iron somewhat like a triangle. This chafing dish should be placed immediately above the fall; while at its bottom there must be a tub half filled with water for receiving the granulated lead. The cullenders are not in contact, but must be parted by burning charcoal in order to keep the lead constantly at the proper temperature, and to prevent its solidifying in the filter. The temperature of the lead bath should vary with the size of the shot; for the largest, it should be such that a bit of straw plunged into it will be scarcely browned, but for all it should be nicely regulated. The height from which the particles should be let fall varies likewise with the size of the shot; as the congelation is the more rapid, the smaller they are. With a fall of 33 yards or 100 feet, from No. 4 to No. 9 may be made; but for larger sizes, 150 feet of height will be required.

Everything being arranged as above described, the workman puts the filter-stuff into the cullender, pressing it well against the sides. He next pours lead into it with an iron ladle, but not in too great quantity at a time, lest it should run through too fast. The shot thereby formed and found in the tub are not all equal.

The centre of the cullender being less hot affords larger shot than the sides, which are constantly surrounded with burning charcoal. Occasionally, also, the three cullenders employed together may have holes of different sizes, in which case the tub may contain shot of very various magnitudes. These are separated from each other by square sieves of different fineness, 10 inches broad and 16 inches long, their bottoms being of sheet iron pierced with holes of the same diameter as those of the cullenders. These sieves are suspended by means of two bands above boxes for receiving the shot; one sieve being usually set above another in consecutive numbers, for instance, 1 and 2. The shot being put into the upper sieve, No. 0 will remain in it; No. 1 will remain in the lower sieve, and No. 2 will, with all the others, pass through it into the chest below. It is obvious that by substituting sieves of successive fineness, shot of any dimensions may be sorted.

In the preceding process the shot has been sorted to size; it must next be sorted to form, so as to separate all the spheroids which are not truly round, or are defective in any respect. For this purpose a board is made use of about 27 inches long and 16 broad, furnished partially with upright ledges; upon this tray a handful or two of the shot to be sorted being laid, it is inclined very slightly, and gently shaken in the horizontal direction, when the globular particles run down by one edge, into a chest set to receive them, while those of irregular forms remain on the sides of the tray, and are reserved to be re-melted.

After being sorted in this way, the shot requires still to be smoothed and polished bright. This object is effected by putting it into a small octagonal cask, through a door in its side, turning upon a horizontal iron axis, with rests in plummer boxes at its ends, and is made to revolve by any mechanical power. A certain quantity of plumbago or black lead is put in along with the shot.

LEAD, CARBONATE OF. See WHITE LEAD.

LEAD, NITRATE OF (*Nitrate de plomb*, Fr.; *Salpeterminerale bleinayd*, Germ.), is made by saturating somewhat diluted nitric acid with oxide of lead (litharge), evaporating the neutral solution till a pellicle appears, and then exposing it in a hot chamber till it be converted into crystals, which are sometimes transparent, but generally opaque white octahedrons. Their spec. grav. is 4.068; they have a cooling, sweetish, pungent taste. They dissolve in 7 parts of cold, and in much less boiling water; they fuse at a moderate elevation of temperature, emit oxygen gas, and pass into oxide of lead. Their constituents are 67.4 oxide and 32.7 a. l. Nitrate of lead is much employed in the chrome yellow style of CALICO-PRINTING; which see.

There are three other compounds of nitric acid and lead oxide; *v. z.* the li-basic, the tri-basic, and the se-basic; which contain respectively 2, 3, and 6 atoms of base to 1 of acid.

LEAD, OXICHLORIDE OF. A white pigment patented by Mr. Hugh Lee Patinson of Newcastle, which he prepares by precipitating a solution of chloride of lead in hot water with pure lime water, in equal measures; the mixture being made with agitation. As the operation of mixing the lime water, and the solution of chloride of lead, requires to be performed in an instantaneous manner, the patentee prefers to employ for this purpose two tumbling boxes of about 16 feet cubic capacity, which are charged with the two liquids, and simultaneously upset into a cistern in which oxichloride of lead is instantaneously formed, and from which the mixture flows into other cisterns, where the oxichloride subsides. This white pigment consists of one atom of chloride of lead and one atom oxide of lead, with or without an atom of water.

LEAD, SALTS OF. The salts of lead, beyond those already named, which enter into any of our manufactures, are few and unimportant. *Ure's Dictionary of Chemistry* should be consulted for them.

LEATHER (*Cuir*, Fr.; *Leder*, Germ.; *Leer*, Dutch; *Læder*, Danish; *Läder*, Swedish; *Cuojo*, Italian; *Cuero*, Spanish; *Kusha*, Russian.). This substance consists of the skins of animals chemically changed by the process called *tanning*. Throughout the civilized world, and from the most ancient times this substance has been employed by man for a variety of purposes. Barbarous and savage tribes use the skins of beasts as *skins*; civilised man renders the same substance unalterable by the external agents which tend to decompose it in its natural state, and by a variety of peculiar manipulations prepares it for almost innumerable applications.

Although the preparation of this valuable substance in a rude manner has been known from the most ancient times, it was not until the end of the last, and the beginning of the present century (1800) that it began to be manufactured upon right principles, in consequence of the researches of Macbride, Deyceux, Seguin, and Davy.

Skins may be converted into leather either with or without their hair; generally, however, the hair is removed.

The most important and costly kinds are comprised under sole leather and upper leather, to which may be added harness leather, belts used in machinery, leather hose, &c., but as far as the tanner is concerned, these are comprehended almost entirely in the kinds known as upper leather.

The active principle by which the skins of animals are prevented from putrefying, and at the same time, under some modes of preparation, rendered comparatively impervious to water, is called tannin, or tannic acid, a property found in the bark of the various species of *Quercus*, but especially plentiful in the gall-nut. When obtained pure, as it may easily be from the gall-nut, by chemical means, tannic acid appears as a slightly yellowish, almost a colourless mass, readily soluble in water; it precipitates gelatin from solution, forming what has been called *tannogelatin*. Tannic acid also precipitates albumen and starch. There can be little difficulty, after knowing the chemical combination just alluded to, in understanding the peculiar and striking change produced on animal substance in the formation of leather. The hide or skin consists principally of gelatin, for which the vegetable astringent tannin has an affinity, and the chemical union of these substances in the process of tanning produces the useful article of which we are treating.

Before entering upon the various processes by which the changes are effected on the animal fibre, it may not be uninteresting to speak of some of the principal astringents used for the purpose of producing these effects.

Bark obtained from the oak-tree is the most valuable and the most extensively used ingredient in tanning, and for a long time no other substance was used in England for the purpose. In consequence of the demand having become very much greater than the supply, and the consequent increase in the price of the article, it became necessary to investigate its properties, in order, if possible, to furnish the required quantity of tanning matter from other sources. Among other substitutes which were tried with some success in other countries may be mentioned *hæth*, *myrtle leaves*, *wild laurel leaves*, *birch-tree bark*, and (according to the *Penny Cyclopædia*) in 1765 oak sawdust was applied in England, and has since been used in Germany for this purpose.

Investigation proved that the tanning power of oak bark consisted in a peculiar astringent property, to which the name of *tannin* has been given, and this discovery suggested that other bodies possessing this property would be suitable substitutes.

According to Sir H. Davy the following proportions of tannin in the different substances mentioned will be found:—"8½ lbs. of oak bark are equal to 2½ lbs. of galls, to 3 lbs. of sumach, to 7½ lbs. of bark of Leicester willow, to 11 lbs. of the bark of the Spanish chestnut, to 18 lbs. of elm bark, and to 21 lbs. of common willow bark."—*Penny Cyclopædia*.

OAK BARK contains more tannin when cut in spring by four and a half times, than when cut in winter; it is also more plentiful in young trees than in old ones. About 40,000 tons of oak bark are said to be imported into this country annually, from the Netherlands, Germany, and ports in the Mediterranean. The quantity of English oak bark used we have no means of ascertaining. It is prepared for use by grinding it to a coarse powder between cast iron cylinders, and haul into the tanpits alternately with the skins to be tanned. Sometimes, however, as will be hereafter noticed, an infusion of the bark in water is employed with better effect.

MEMORA.—The bark and pods of several kinds of *Prosoopia*, the astringent properties of which have rendered them valuable in tanning, are known in commerce by this

1104

1103

name. The *Mimosa* are a division of the leguminous order of plants, which consists of a large number of species, the *Acacia* being the principal. The sensitive plants

belong to this division. The propolis is found in India and South America; the genus consists both of shrubs and trees.

VALONIA.—The oak which produces this acorn is the *Quercus Fagifolia*, or great prickly cupped oak (figs. 1101, 1103). These are exported from the Morro and Levant; the husk contains abundance of tannin.

CATECHU, or Terra Japonica, is the inspissated extract of the *Azoreum catechu*. At the time the sap is most perfectly formed the bark of the plant is taken off, the tree is then felled, and the outer part removed; the heart of the tree, which is brown, is cut into pieces and boiled in water; when sufficiently boiled it is placed in the sun, and subject to various manipulations, gradually dried. It is cut into square pieces, and much resembles a mass of earth in appearance; indeed it was once considered to be such, hence the name *Terra Japonica*.

We give Sir H. Davy's analysis; the first numbers represent Bombay, the second Bengal catechu:—

Tannin	-	-	-	-	-	169	-	97
Extractive	-	-	-	-	-	68	-	73
Mucilago	-	-	-	-	-	13	-	16
Impurities	-	-	-	-	-	10	-	14

This astringent is also obtained from the *Uncaria Gambir*.

DALBERG is a leguminous plant of the genus *Casalpinia*, *C. coriaria*. The legumes of this species are extremely astringent, and contain a very large quantity of tannic and gallic acid; they grow in a very peculiar manner, and become curiously curled as they arrive to perfection. The plant is a native of America, between the tropics.

1106

Fig. 1106.

SEMAEN is a plant belonging to the genus *Illus*; several of the species have astringent properties; *Illus cotinus* and *Illus coriaria* are much used in tanning; the bark of the latter is said to be the only ingredient used in Turkey for the purpose of converting gelatin into leather. That used

in this country is ground to a fine powder, and is extensively applied to the production of bright leather, both by tanners and curriers.

Many other vegetable products have been from time to time proposed, and to some extent adopted for the same end, but they need not be enumerated.

The process first attended to by the tanner is simply to soak the skin or hide in water; those from the home market may be said to be washed merely, as they remain in water only a few hours; while hides imported from foreign countries, and which have been preserved by salting or drying, and especially the latter, require soaking for a longer period, in order to render them supple, and beating or rubbing materially assists in bringing them to the required condition.

After removing the horns, the softened or recent hides are laid in a heap for a short time, after which they are suspended on poles in a close room called a smoke-house, heated somewhat above the common temperature by a smouldering fire. In these circumstances, a slight putrefaction supervenes, which loosens the epidermis, and renders the hair easily detachable. This method for removing the hair is by no means general in this country. The plan adopted is to place the hides in a large vat or pit containing milk of lime, in which they must be moved frequently, to allow the lime to act equally on every part. When the menstruum has taken proper effect, the hair is easily removed, and for this purpose the hide is spread out, and a blunt tool is worked over the surface. The hair being removed, the hide is washed in water to cleanse it from the lime, which must be most thoroughly effected.

The heaviest hides are for the most part tanned for sole leather, and as the thinner parts are cut off previous to their being prepared for sale, they have received the name of *butts* or *backs*; the various processes through which these pass will be first described.

After removing the hair and washing, the hides are placed on a convex beam (fig. 1107), and worked with a concave tool with two handles (fig. 1108), in order to remove any flesh or fatty matter which may adhere to them; this being done they are worked on the same beam, on the grain side, to drive out the grease and remove any remaining hair. The *flaskings* are pressed into cakes and sold for making glue, as are all such portions of the hide or skin as cannot be conveniently worked. The hair is sold to plasterers, to be used in their mortar, and the tails, also for the hair, to sofa-makers and others requiring such materials.

Such hides as are designed for machinery purposes are next immersed in a pit containing water impregnated with sulphuric acid, the acid varying from $\frac{1}{10}$ to $\frac{1}{20}$ of the mixture. This process is called *raising*, because it distends the pores, and makes the fibres swell, so as to become more susceptible of the action of tanning infusions. Forty-eight hours in general suffice for this operation, but more time may be safely taken. From the term *raising* it will be concluded that the substance of the hide is increased, and this is the fact; but as the gelatine is not increased it is said that the shoemaker's hammer would condense the leather so much that it would lose any supposed advantage arising out of this increase in thickness. There is, however,

a method of augmenting the substance of sole leather called *puffing*, which, when once communicated, appears to exist permanently; the process is known to a small extent only, and the material is said to be considerably injured by this mode of preparation.

When the hides are sufficiently raised, they are transferred to a pit supplied with a weak infusion of bark; here they are handled, at first several times a day, that is, they are drawn out of the pits, or moved up and down in the liquor, to prevent the grain from being drawn into wrinkles. As the case, or tanning infusion, takes effect, they are put into pits containing stronger liquors, and after a month or six weeks they are placed in a pit, in which they are stratified with oak bark, ground by a proper mill into a coarse powder. The pit is then filled with an infusion of bark. In a month or five weeks the tanning and extractive matter of the bark will have intimately combined with the animal fibre; the pit, exhausted of its virtue, must be renewed by taking out the spent bark and repeating the dose as in the first instance. The hides, which were placed at the top of the pit at first, are now put into the bottom, to equalise the action. In about three months this also is spent, and the process being repeated two or three times more the operation is complete. The hides are now removed from the pit, and hung up in a shed. In the progress of drying they are compressed with a steel tool, and afterwards they are subjected to the action of a brass roller. The steel tool is called a *pin*; it is of a triangular shape (fig. 1109), with the sides scooped out (fig. 1110), presenting three blunt edges. The butt is thrown across a pole,

and the workman taking the pin by the handles *a, a* (fig. 1109), presses it forcibly over the grain side of the leather; after carefully compressing every part in this way, the butt is laid upon a flat bed of solid wood-work, prepared for the purpose, and the brass roller is worked backward and forward until every portion is sufficiently compressed (fig. 1111). The roller *a* is a cylinder varying from 9 to 12 inches in length, and from

7 or 10 inches in diameter; & is an open box over the roller, into which weights are placed to make the necessary pressure, ten or twelve being frequently used for the purpose; & c. c. forms a frame for driving the roller from the bed to the leather; & in the hands of which the machine is worked. When the preparation is completed, the only thing remaining to be done is properly to dry the leather, and then to fit it for the market.

Some manufacturers place on the bottom of the tan pits five or six inches of spent bark, and two or three inches of fresh bark over it, then a hide, and an alternating bark and a hide, until they get tolerably full, reserving a small space at the top for a thicker layer of bark, over which wetted boards are laid, to condense the water down into the tanning infusion.

The operation of tanning cow leather by the above method occupies a year or more, the time depending on the use and condition of the hide.

A perfect leather is recognised by its colour, which should have a greenish marbled appearance, without any white streak in the middle.

Crop hides are manufactured very much like butts, that is to say, they are piled in much of time until the hair is sufficiently loosened, equality of colour being preserved by occasionally moving them to the centre beam; they are then cleared of the hair and other impurities by the *straking knife*, worked on the convex beam already described; they are then freed from lime by thorough washing. The next process is to transfer them into a weak lime frame, in which they are transferred to other pits with stronger ones; and the while they are frequently handled, that is, moved up and down in the infusion. After a month or six weeks they are subjected to a mixture of ground oak bark and stronger lime in other pits, in a series of which they are progressively subjected during two or three months.

The hides are next put into large vats called *layers*, in which they are thoroughly stratified, with more bark and a stronger infusion. After about six weeks they are taken out of these vats, and subjected to a new charge of this material, and allowed to lay some two months; this process is repeated until or twice more, till the skins are thoroughly tanned. They are then slowly dried in the shed, and fitted for the market. Although in general the stouter and most valuable part hides are used as sole leather (without any that they have not been employed by the tanner, as to the case of *lows*), yet many are appropriated to other purposes by the currier, and the lighter cow hides are manufactured for the upper leather of boots, shoes, water boots, &c.

The process of tanning *alias* (as calves, seals, &c.) next claims attention. These are placed in the lime pits until the hair can be easily removed, a process which requires about ten or twelve days; this being accomplished, they are next washed in water so as completely to remove the lime, as far as washing can secure its removal, and then immersed in a *lixivium* of pigeon's dung, dog's dung, or matters of a like nature, in this state they remain about ten or twelve days, the state of the atmosphere rendering the process quicker at one time than another, here also they are frequently handled, and worked on both sides on the convex beam. The working, joined to the action of the peculiar *lixivium*, serves to separate the remaining lime, oil, and glutinous matter, and at the same time to render the skin pliant, soft, and ready to imbibes the tanning principle. It is important that great attention should be paid to the process just described, as too short a period would produce a hard and crisp leather, while a few hours more than is necessary makes the article coarse and spongy, both of which conditions should be very carefully guarded against.

The skins are next removed to a pit containing a weak solution of bark, in which they undergo nearly the same treatment as *crop hides*, but they are not commonly stratified in the layers. About three months is usually occupied in tanning calves, but of course the stouter the skin the more will be the time required. When dried they are disposed of to the currier, who dresses them for the upper leathers of boots, shoes, and a variety of other purposes. It is not unusual for the lighter cow hides to be treated like calfskins.

Horse hides are also treated like calfskins; but as the horse hide, with the exception of the part on and near the animal's rump, produces a thin leather, it is usual, before subjecting the hide to the action of the bark, to cut out what is called the *butt*, which is tanned separately, and frequently used as an inferior sole leather. It is also to be remarked that horse hides and *lows* (the hides of small foreign cattle) are frequently subjected to a process called *bate skining*, in which the stout parts are reduced by a currier's knife previous to tanning, the object being to secure the complete infiltration of the animal fibres by the tannin in every part of the hide in the same time.

Sheepskins are usually prepared before the wool is removed, and before the tanning process is commenced, to get rid of the fatty matter contained in them, and which is not readily removed by ordinary working.

In all the above processes, as the animal skins on the surface of the skin absorb more readily the tanning liquor, and therefore the first is a certain device, their parts are made of the same material, especially of thick hide, it being an almost indispensable requisite to the success of every kind of operation, and preventing the penetration of the air. The first man for ever who appears to have employed effective means for the purpose of accelerating the chemical action was Francis G. Spalding, who in April, 1818, obtained a patent for the following operation. — After the hides are freed from the hair, &c. in the usual way, they are usually inspected as to the condition, and if any holes be found, they are carefully sewed up, so as to be water tight. Two frames of wood are provided of equal dimensions, fitted to each other, with the edges of the frames held together by screw bolts. A skin about to be tanned is now laid upon the frame, and stretched over its edges, then the second frame is to be placed upon it, so that the edges of the two frames may pinch the skin all round and hold it securely; another such skin is then stretched over the upper surface of the second frame, in the manner, and a third frame being set upon this, confine the second skin. The three frames are then pushed tightly together by a series of screw bolts, passing through their outer edges, which fix the skin in a proper manner for being operated upon by the tanning liquor.

A space has been thus formed between the two skins, into which, where the frames are set upright, the liquor is introduced by means of a pipe from the cistern above, while the air is permitted to escape by a stopcock below. The cock must of course be closed whenever the bag is filled; but the one above is left open to maintain a communication with the liquor cistern, and to allow the hydrostatic pressure to force the liquor through the cutaneous pores by a slow infiltration, and thus to bring the tannin into contact with all the fibres indiscriminately. The action of this process is evinced by a constant perspiration on the outer surfaces of the skins.

When the tanning is completed, the upper stopcock is closed, and the under is opened to run off the liquor. The frames are now removed, the bolts are unscrewed, and the pinched edges of the skins pared off; after which they are to be dried and finished in the usual manner.

A modification of this ingenious and effectual process was made the subject of a patent by William Blake, of Westminster, tanner, in October, 1831. The hides, after the usual preparatory process, are immersed in a weak tan liquor, and by frequent handling or turning over, receive an incipient tanning before being submitted to the impregnation plan. Two hides, as nearly of the same size and shape as possible, are placed grain to grain, when their corresponding edges are sewed firmly together all round by shoemaker's waxed thread, so as to form a bag sufficiently tight to hold tan liquor. This bag must then be suspended by means of loops sewed to its shoulder end, upon poles, in such a manner that it may hang within a wooden-barred rack, and be confined laterally into a hook form. About an inch of the bag is left unsewed at the upper end, for the purpose of introducing a funnel through which the cold tan liquor is poured into the bag till it be full. After a certain interval, which varies with the quality of the hides, the outer surface becomes moist, and drops begin to form at the bottom of the bag. These are received in a proper vessel, and when they accumulate sufficiently may be poured back into the funnel; the bag being thus, as well as by a fresh supply from above, kept constantly distended.

When the hides are observed to feel hard and firm, while every part of them feels equally damp, the air of the tanning apartment, having been always well ventilated, is now to be heated by proper means to a temperature gradually increasing from 70° to 100° of Fahrenheit's scale. This heat is to be maintained till the hides become firmer and harder in all parts. When they begin to assume a black appearance in some parts, and when the tan liquor undergoes little diminution, the hides may be considered to be tanned, and the bag may be emptied by cutting a few stitches at its bottom. The outer edges being pared off, the hides are to be finished in the usual way. During their suspension within the racks, the hides should be shifted a little at intervals, to prevent the formation of furrows by the bars, and to facilitate the equable action of the liquor.

By this process the patentee says, that a hide may be tanned as completely in ten days as it could be in ten months by the usual method.

Messrs. Knowles and Duesbury obtained a patent in August, 1826, for accelerating the impregnation of skins with tannin, by suspending them in a close vessel, from which the air is to be extracted by an air pump, and then the tanning infusion is to be admitted. In this way, it is supposed to penetrate the hide so effectually as to tan it uniformly in a short time.

Danish leather is made by tanning lamb and kid skins with willow bark, whence it derives an agreeable smell. It is chiefly worked up into gloves.

Of the tanning or dressing of skins for shoes, and other deep leather.

The operations of this art are, 1, washing the skins, 2, properly treating them with lime, 3, taking off the fluff, 4, treatment in the leather camp.

A shed erected upon the side of a stream, with a pattern of water for washing the skins, wooden frames for cleaning them, with the back of the tanning house; pumps for removing the fibres of deer-skins, with a plough for digging the skins in the pits; a lime pit, a pile with a bar to lift the end of it into the tanning house; a rolling-pin, from 13 to 15 inches long, thickened in the middle. Such are some of the utensils of a tanning establishment. There must be provided also a table for applying the oil to the skins; a fluting mill, worked by a water-wheel or other power, a dressing-jug, a press for squeezing out the fatty matter; a stove; plants suspended upon bars, for stretching the skins, &c.

Fresh skins must be washed immediately after being washed, and then dried, unless they ferment, and contract cuts and holes, which, if not cured in certain points, so as to open up and tear under the toes. When removed to the dry state they should be steeped in water for two days, and then treated as fresh skins. They are next strongly rubbed on the convex side with a round-edged knife, in order to remove the plants. The rough parts are removed by the fluting knife. One workman can in this way prepare 200 skins in a day.

The flesh side of each being rubbed with a cold cream of lime, the skins are piled together with the woolly side of each pair outward, and the flesh side in contact. They are left in this state for a few days, till it is found that the wool may be easily removed by plucking.

They are next washed in running water, to separate the greater part of the lime, stripped of the wool by the fluting knife, and then freed from it by means of the rolling-pin, or sometimes by rubbing with a waterstone. Unless they be fluted soon after this treatment with lime, they do not well admit of this operation, and, in fact, as they are apt to get hard.

They are now steeped in the milk of lime-pit, in order to swell, soften, and remove them; afterwards in a weak pit of old lime-water, from which they are taken out and drained. This steeping and draining upon inclined tables, are repeated frequently during the space of 3 weeks. Truly the skins of young animals, or those of inferior value are now, sometimes the wool is left on, as for horse-gear, &c.

The skins, after having been well softened in the steep, are rubbed on the outside with a whetstone set in a wooden case with two handles, in order to cleanse them completely by removing any remaining filaments of wool. These skins are rubbed with the pin in the direction of their breadth, to give them suppleness; but sheep skins are felled with water alone. They are now ready for the brunoise, which is done by mixing 40 lbs. of bran with 20 gallons of water, and keeping them in this fermentable mixture for three weeks—with the addition, if possible, of some old bran water. Here they must be frequently turned over, and carefully watched, as it is a delicate operation. In the course of two days in summer, and eight in winter, the skins are said to be raised, when they sink in the water. On coming out of the bran, they are ready for the white stuff; which is a bath composed of alum and sea-salt. Twelve, fourteen, and sometimes eighteen pounds of alum for 100 skins, form the base of the bath; to which two and a half pounds of salt are added in winter, and three in summer. These ingredients are introduced into a copper with twelve gallons of water. The salt aids in the whitening action. When the solution is about to boil, three gallons of it are passed through the cullender into a basin, in this 26 skins are worked one after another, and after draining, they are put together into the bath, and left in it for ten minutes to imbibe the salts. They are now ready to receive the paste. For 100 skins, from 13 to 15 pounds of wheat flour are used, along with the yolks of 30 eggs. After having warmed the alum bath through which the skins have been passed, the flour is dusted into it, with careful stirring. The paste is well kneaded by the gradual addition of the solution, and passed through the cullender, whereby it becomes as clear as honey. To this the yolks being added, the whole is incorporated with much manual labour. The skins are worked one after another in this paste; and afterwards the whole together are left immersed in it for a day. They are now stretched and dried upon frames, in a proper apartment, during from 8 to 15 days, according to the season.

The effects of the paste are to whiten the skins, to soften them, and to prevent them from the hardening influence of the atmosphere, which would naturally render them brittle. They would not bear working upon the ordinary iron, but for the emulsion which has been introduced into their substance. With this view they are dipped in a tub of clear water during five or six minutes, and then spread and worked upon the board. They are increased by this means in length, in the proportion of 3 to 2. No hard points must be left in them. The whiteness is also better brought out by this

of the skin, which is performed upon the flesh side. The softening tool is an iron plate, about one foot broad, rounded over at one end, and upon an upright beam, the other high, which is fixed to the end of a strong wooden plank, 4 feet long, and 1 broad. This plank is heavily loaded, to make it immovable upon the floor. Sometimes the skins are first spread over an undressed plank upon the floor, and worked well with the two handled knife, for the purpose of removing the first and second epidermis, and the flour and arrow flour is the French name. They are then dried while stretched by hands and straps. When dry they are worked on the stretching iron, or they are occasionally polished with pumice stone. A delicate yellow tint is given by a mixture made of two parts of white sugar and one of oil, applied in a powdered state, and well worked in upon the grain side. After being polished with pumice, they are smoothed with a hot iron, as the islands now do linen, whereby they acquire a degree of gloss, and are ready to be delivered to the glazer.

For harness, the best sheepskins are selected, and such as are covered with the longest and most bran full wool. They are stretched in water, in order to be cleaned and polished; after which they are tanned inside by the stretching knife. They are now stretched in an old brass pit for 3 or 4 days, when they are taken out and washed. They are next suspended to the white or stone bath, the wool being carefully folded so that a small quantity of oil can be used for it. The paste is made as for the dressed skins, and is evenly spread upon the flesh side, and left upon them for 12 hours, and then washed. They are then hung up to dry. They are next mounted by sprinkling cold water upon them, folded up, piled in a heap, and covered with heavy stones, in which state they remain for two days. They are next opened with a round knife upon the horse, and subjected to the stretching iron, being worked between the hands. They are dried with the floor underneath, in the sun if possible, and are finished upon the stretching iron.

Half and lambskins with their hair and wool are worked nearly in the same manner; only the thicker the skin, the stronger the oil in both ought to be. One pound of lard and one of salt are required for a single calf skin. It is left for days in this bath, after which it is worked upon the stretching, then tanned. When half dry, the skins are opened upon the horse. In eight days of ordinary weather, they may be completely dressed. Lamb skins are sometimes steeped during eight days in a bath prepared with unbolthead rye flour and cold water, in which they are daily moved about two or three times. They are then dried, stretched upon the iron, and stretched upon the fleecy side.

Shamoy, or Shamoy leather — The skins are first washed, lined, dressed, and branched as above described. They are next *efflowered*, that is deprived of their epidermis by a blunt knife, blunt in its middle part, upon the convex horse-beam. The cutting part serves to remove all excrescences, and to equalise the thickness, while the blunt part softens and smooths. The skins of goats, does, and chamois are always treated in this way. They are next subjected to the fermenting brass steep for one or two days, in ordinary weather; but in hot weather for a much shorter time, sometimes only moving them in the musty brass liquor for a few minutes. They are lastly wrung at the peg, and subjected to the falling mill.

When the skins have been sufficiently swelled and supplied by the branning, they may receive the first oil as follows: a dozen skins being stretched upon the table, the fingers are dipped in the oil, and shaken over the skins in different places, so as to impart enough of it to rub into the whole surface slightly, by friction with the palms of the hands. It is to the outside or grain that the oil is applied. The skins are folded four together, so as to form balls of the size of a hog's bladder, and thrown into the trough of the falling mill, to the number of twelve dozen at once. Here they remain exposed to the heater for two, three, or four hours, according to their nature and the state of the weather. They are taken out, stretched, oiled, and again folded. The stretching and folding are repeated several times, with more or less frequent oilings. Any cheap animal oil is employed.

After these operations, the skins require to be subjected to a fermenting process, to dilate their pores, and to facilitate their combination with the oil. This is performed in a chamber only 8 feet high, and 10 or 12 feet square. Poles are suspended horizontally a few inches from the ceiling, with hooks fixed in them to which the skins are attached. A somewhat elevated temperature is maintained, and by a stove if need be. This operation requires great skill and experience.

The remainder of the epidermis is next removed by a blunt concave knife and the horse, whereby the surface is not cut, but rather forcibly scraped.

The skins are now scoured to carry off the redundant oil; which is effected by a potash lye, or E. Hamel, heated no hotter than the hand can bear. In this they are stirred briskly, steeped for an hour, and lastly wrung at the peg. The soapy liquor thus expelled is used for inferior purposes. The clean skins after being dried are finished first on the stretching iron, and then on the horse or stretching frame.

Leather of Hungary.—This is manufactured by suspending strips of hides with claws, common salt, and yeast, by a rapid process which is usually restricted to the space of two months. The workshop is divided into two parts: 1. A kind of the pole of a narrow furnace with a wooden frame, having bars, and other small poles. In one corner is a furnace with a boiler for heating the steam, a vat for dissolving the skins in the solution, and several subsidiary tubs. 2. A chamber, 6 feet high, by 15 feet square, capable of being made very tight, for preserving the heat. In one corner is a copper boiler, of cast-iron, into which an iron grate is placed, and a small square. This is covered with a floor. At each side of the boiler are large tables, which occupy its whole length, and on which the leather is spread to receive the steam. The upper part below the ceiling is filled with poles for hanging the leather open to be heated. The door is made to shut perfectly close.

The first operations are analogous to those of tanning and tawing; the skins being washed, cut in halves, shaved, and composed of 24 hours in the river. They are then cleaned with 3 or 4 pounds of alum, and 25 pounds of salt, for a pound of hide which weighs from 50 to 60 pounds. The common salt withdraws the effect of the alum, attracts the moisture of the air, and preserves the supple nature of the skin. When the alum and salt are dissolved, hot water is poured upon the hides placed in a vat, and they are trampled upon by a workman walking repeatedly from one end of the vat to the other. They are then transferred into a smaller vat containing some hot water, and similarly trampled upon. They are next steeped for eight days in alum water. The same round of operations is repeated a second time.

The skins are now dried either to the air, or a stove room; but before being quite dry, they are doubled together, well stretched to take out the wrinkles, and put up. When dry, they are again trampled to open the pores as well as to remove the skin plant, after which they are whitened by exposure to the sun.

Tallow of inferior quality is employed for greasing the leather. With this view the hides are hung upon the poles in the close stove room, then laid upon the table, and lubricated with the tallow melted till it begins to crackle. This pole is laid on another table, is there covered with a second, similarly greased, and so forth. Three pounds of fat are commonly employed for one piece of leather.

When the thirty strips, or fifteen hides, passed through the grease in one operation are completed, two workmen take the first piece in their hands, and stretch it over the burning charcoal on the grate for a minute with the flesh side to the fire. The rest are passed over the flame in like manner. After flowing the pieces are immediately laid on an inclined table exposed to the fire, where they are covered with a cloth. They are finally hung upon poles in the air to dry; and if the weather be warm, they are suspended only during the night, so as to favour the hardening of the grain. Instead of the alum bath, M. Caraudan has employed with advantage a steep of dilute sulphuric acid.

Russian leather.—The Russians have long been possessed of a method of making a peculiar leather, called by them *jarten*, dyed red with the aromatic saunders wood. This article has been much sought after, on account of not being subject to mould in damp situations, being proof against insects, and even repelling them from the vicinity of its odour. The skins are freed from the hair or fleece, by steeping in an alkali too weak to act upon the animal fibres. They are then rinsed, soaked for a longer or shorter time according to their nature, and fermented in a proper steep, after having been washed in hot water. They are taken out at the end of a week, but they may be steeped a second time if deemed necessary, to open their pores. They are now cleaned by working them at the horse on both the flesh and grain sides.

A paste is next composed, for 200 skins, of 35 pounds of rye flour, which is set to ferment with yeast. This dough is worked up with a sufficient quantity of water to form a bath for the skins, in which they are soaked for 48 hours; they are then transferred into small tubs, where they remain during fifteen days, after which they are washed at the river. These operations serve to prepare the skins for absorbing the astringent juices with uniformity. A decoction of willow bark (*Salix cinerea* and *Salix caprea*) being made, the skins are immersed in the boiler whenever the temperature of the liquor is sufficiently lowered not to injure the animal fibres, and handled and pressed for half an hour. This manipulation is repeated twice daily during the period of a week. The tanning infusion is then renewed and applied to the same skins for another week; after which, being exposed to the air to dry, they are ready for being dyed, and then carried with the empyreumatic oil of the bark of the birch tree. To this substance the Russian leather owes its peculiarities. Many modes have been prescribed for preparing it; but the following is the one practised in Russia.

The whitish membranous epidermis of the birch, stripped of all woody parts, is introduced into an iron boiler, which, when stuffed full, is covered tight with a vat and

iron still, having a pipe rising from its centre. A second boiler into which this pipe passes without reaching its bottom, is set over the first, and is luted to it at the edges, after the two are held together. They are then inverted, so that the upper one contains the bark bark. The under half of this apparatus is sunk in the earth, the surface of the upper boiler is covered over with a clay lute, then surrounded with a fire of wood, and exposed to a red heat, till the distillation be completed. This operation, though rude in appearance, and wasteful of wood, answers its purpose perfectly well. The iron cylinder apparatus used in Britain for distilling wood vinegar would, however, be much more convenient and productive. When the above ludes are united, there is found in the upper boiler a very light powder of charcoal, and in the under one, which served as a receiver, there is an oily, brown, empyreumatic fluid, of a very strong smell, which is mixed with the tar, and which flows over a small quantity of crude vinegar. The former matter is the oil employed to impregnate the skins, by working it into the flesh side with the carrier's tumb. It is difficult to make this oil penetrate with uniformity; and the Romans do not always succeed in this process, for they turn out many skins in a spotted state. This oil is at present burned in France by distilling the bark bark in copper stills, and condensing the products by means of a glass placed in cold water. About ten per cent. of the weight of the bark is extracted.

The skins which are oil once equally before they are fully dry. Care must be taken not to apply too much of it, for fear of its passing through and staining the grain side of the leather. Chevreul has investigated the chemical nature of this odorous substance, and finding it to be a peculiar compound, has called it *betanhar*.

In the *Franklin's Almanac* for February, 1844, Mr. Gideon Lee has published some judicious observations on the process of tanning. He believes that much of the animal gelatine of the hides is never combined with the tannin, but is wasted; for he thinks that 100 lbs. of perfectly dry hide, when cleaned from extraneous matter, should, on chemical principles, afford at least 100 lbs. of leather. The usual preparation of the hide for tanning he believes to be a wasteful process. In the liming and liming, or the unhairing and the cleansing, the general plan is first to steep the hides in milk of lime for one, two, or three weeks, according to the weather and texture of the skin, until the hair and epidermis be so loosened as to be readily removed by rubbing down, by means of a knife, upon a beam or block. Another mode is to compound the hides in a close chamber, heated slightly by a smouldering fire, till the epidermis gets loosened by ineffectual putrefaction. A third process, called sweating, used in tanneries, consists in laying the hides in a pack or pile, covered with tan, to promote fermentative heat, and to loosen the epidermis and hairs. These plans, especially the two latter, are apt to injure the quality of the hides.

The *hate* consists in steeping the haired hides in a solution of pigeon's dung, containing, Mr. Lee says, muriate of ammonia, murate of soda, &c.; but most probably phosphate of ammonia and lime, with urate of ammonia, and very fermentable animal matter. The dry hides are often subjected first of all to the operation of the fulling-stocks, which opens the pores, but at the same time prepares them for the action of the liming and beating also for the introduction of the tanning matter. When the fulling is too violent, the leather is apt to be too limber and thin. Mr. Lee conceives that the liming is injurious, by carrying off more or less of the gelatine and albumen of the skin. High limed leather is loose, weighs light, and wears out quickly. The subsequent fermentation in the bating aggravates that evil. Another process has therefore been adopted in New York, Maine, New Hampshire, and some parts of Philadelphia, called, but incorrectly, coal sweating, which consists in suspending the hides in a subterranean vault, in a temperature of 50 Fahr., kept perfectly damp, by the trickling of cold spring water from points in the roof. The hides being first soaked, are suspended in this vault from 6 to 12 days, when the hair is well loosened, by the mere softening effect of moisture, without fermentation.—H. M.

LEATHER, MOROCCO. (*Marroquin, Fr.; Saffian, Germ.*) Morocco leather of the finer quality is made from goat-skins tanned with sumach; inferior morocco leather (roan) from sheep skins. The goat skins as imported are covered with hair; to remove which they are soaked in water for a certain time, and they are then subjected to the operation called breaking, which consists in scraping them clean and smooth on the flesh side, and they are next steeped in lime pits (milk of lime) for several days, during which period they are drawn out, with a hook, from time to time, laid on the side of the pit to drain, and replunged alternately, adding occasionally a little lime, whereby they are eventually deprived of their hair. When this has become sufficiently loose, the skins are taken out one by one, laid on convex beams, the work benches, which stand in an inclined position, resting on a stool at their upper end, at a height convenient for the workman's breast, who scrapes off the hair with a concave steel blade or knife, having a handle at each end. When unhaired, the skins are once more soaked in milk of lime for a few days, and then scraped on the flesh

side to render it very even. For removing the lime which obstructs their pores, and would impede the tanning process, as well as to open these pores, the skins are steeped in a warm semi-putrid alkaline liquor, made with pigeons' and hens' dung diffused in water. Probably some very weak acid, such as fermented bran water, would answer as well, and not be so effective to the workmen. (In Germany the skins are first washed in a barrel by a revolving axle and discs.) They are again scraped, and then sewed into bags, the grain outward, like bladders, leaving a small orifice, into which the neck of a funnel is inserted, and through which is poured a certain quantity of a strong infusion of the sumach; and they are now rendered tight round the orifices, after being filled out with air, like a blown bladder. A parcel of these inflated skins are thrown into a very large tub, containing a weaker infusion of sumach, where they are rolled about in the middle of the liquor, to cause the infusion within to act upon their whole surface, as well as to expose their outanles uniformly to the tanning action of the bath. After a while these bladder skins are taken out of the bath, and piled over each other upon a wooden rack, whereby they undergo such pressure as to force the enclosed infusion to penetrate through their pores, and to bring the tannin of the sumach into intimate contact, and to form a chemical combination with the skin fibres. The tanning is completed by a repetition of the process of introducing some infusion or decoction into them, blowing them up, and floating them with agitation in the bath. In this way goat skins may be well tanned in the course of one day.

The bags are next undone by removing the sewing, the tanned skins are scraped as before on the carriers' bench, and hung up in the drying loft or shed; they are said now to be "in the crust." They are again moistened and smoothed with a rubbing tool before being subjected to the dyeing operations, in which two skins are applied face to face to receive the dye to one of their surfaces only, for the sake of economising the dyeing materials, which may be of several different colours. The dyed skins are graded by being strongly rubbed with a ball of box wood, finely grooved on its surface.

Preparatory to being dyed, each skin is sewed together edgewise, with the grain on the outside, and it is then mordanted either with a solution of tin, or with alum water. The colour given by cochineal, of which from 10 to 12 ounces are required for a dozen of skins. The cochineal being boiled in water along with a little tartar or alum for a few minutes, forms a red liquor, which is filtered through a linen cloth, and put into a clean cask. The skins are immersed in this bath, and exposed to it for about half an hour; they are taken out and beaten, and then subjected to a second immersion in the cochineal bath. After being thus dyed, they are rinsed and tanned with Sicilian sumach, at the rate of two pounds for a skin of moderate size. The process is performed in a large tub made of white wood, in the liquor of which the skins are floated like so many bladders, and moved about by manual labour during four hours. They are then taken out, drained, and again subjected to the tanning liquor; the whole process requiring a space of twenty-four hours. The skins are now unstitched, rinsed, filled with beetles, drained, rubbed hard with a copper blade, and lastly hung up to dry.

Some manufacturers brighten the colour by applying to the surface of the skins, in a damp state, a solution of carmine in ammonia with a sponge; others apply a decoction of saffron to enliven the scarlet tint. At Paris, the morocco leather is tanned by agitation with a decoction of sumach in large casks made to revolve upon a horizontal axle, like a barrel churn. White galls are sometimes substituted for sumach; a pound being used for a skin. The skins must be finally cleaned with the utmost care.

The black dye is given by applying with the brush a solution of red acetate of iron to the grain side. Blue is communicated by the common cold indigo vat; violet, with a light blue followed by cochineal red; green, by Saxon blue followed by a yellow dye, usually made with the chopped roots of the barberry. This plant serves also for yellows. To dye olive, the skins are first passed through a weak solution of green vitriol, and then through the decoction of barberry root, containing a little Saxon blue. Peach colour is communicated by logwood with a little alum; which may be modified by the addition of a little Brazil wood. In all these cases, whenever the skins are dyed, they should be rinsed, wrung, or rather drained, stretched upon a table, then besmeared on the grain side with a film of linseed oil applied by means of a sponge, in order to promote their glossiness when carried, and to prevent them becoming horny by too rapid drying.

The last process in preparing morocco leather is the currying, which brings out the lustre, and restores the original suppleness. This operation is practiced in different manners, according to the purpose the skins are to serve. For pocket-books, portfolios, and case-making in general, they must be thinned as much as possible upon the flesh side, moistened slightly, then stretched upon the table, to smooth them; dried

again, moistened, and lastly passed two or three times through the cylinder press in different directions, to produce the crossing of the grain. The skins intended for the shoemaker, the saddler, the book-binder, &c., require more pliancy, and must be differently curried. After being thinned, they are glazed with a polisher while still moist, and a grain is formed upon the flesh side with the roughened lead plate or grainer of the curriers, called in French *pommelle*; they are glazed anew to remove the roughness produced by the pommel, and finally grained on the flesh side with a surface of cork applied under a pommel of white wood.

TAWING OF SKINS. (*Mégisserie*, Fr.; *Wassgerberei*, Germ.) The kid, sheep, and lamb skins, are cleaned as has been already described. In some factories they receive the tanning power of the submuriate of alumina (from a solution of alum and common salt) in a large barrel-churn apparatus, in which they are subjected to violent agitation, and thereby take the *alumine* in the course of a few minutes. In other cases, where the yolks of eggs are added to the above solution, the mixture, with the skins, is put into a large tub, and the whole trampled strongly by the naked feet of the operator, till the emulsion of the egg be forced into the pores of the skin. The tawed skins, when dry, are "staked," that is stretched, scraped, and smoothed by friction against the blunt edge of a semi-circular knife, fixed to the top of a short beam of wood set upright. The workman holding the extremities of the skin with both hands, pulls it in all directions forcibly, but skilfully, against the smoothing "stake."

In an entertaining article on tanning in the 11th vol. of the *Penny Magazine*, at page 215, the following description is given of one of the great tawing establishments of London.

"In the production of 'imitation' kid leather, the skin of lambs is employed; and for this purpose lamb-skins are imported from the shores of the Mediterranean. They are imported with the wool yet on them; and as this wool is valuable, the leather manufacturer removes this before the operations on the pelt commence. The wool is of a quality that would be greatly injured by the contact of lime, and therefore a kind of natural fermentation is brought about as a means of loosening the wool from the pelt." The following is a description of one of the buildings. "On the ground floor, a flight of stone steps leads down to a range of subterranean vaults or close rooms, into which the lamb-skins are introduced in a wet state, after having been steeped in water, 'broken' on the flesh side, and drained. The temperature of these rooms is nearly the same all the year round, a result obtained by having them excluded as much as possible from the variations of the external atmosphere; and the result is, that the skins undergo a kind of putrefactive or fermenting process, by which the wool becomes loosened from the pelt. During this chemical change ammonia is evolved in great abundance; the odour is strong and disagreeable; a lighted candle, if introduced, would be instantly extinguished, and injurious effects would be perceived by a person remaining long in one of the rooms. Each room is about ten feet square, and is provided with nails and bars whereon to hang the lamb-skins. The doors from all the rooms open into one common passage or vault, and are kept close, except when the skins are inspected. It is a point of much acuity to determine when the fermentation has proceeded to such an extent as to loosen the wool from the pelt; for if it be allowed to proceed beyond that stage, the pelt itself would become injured.

When the fermentation is completed, generally in about five days, the skins are removed to a beam, and there "skimed," that is, scraped on the flesh side, to remove a slimy substance which exudes from the pores. The wool is then taken off, cleaned, and sold to the hatters, for making the bowles of common hats. The stripped pelts are steeped in lime-water for about a week, to kill the grease; and are next "steaked on the beam." After being placed in a "drench," or a solution of sour bran for some days to remove the lime and open the pores, the skins are skimed, and subjected to nearly the same processes as the true kid-skins. These Mediterranean lamb-skins do not in general measure more than about 24 inches by 12; and each one furnishes leather for two pairs of small gloves. These kinds of leather generally leave the leather-dresser in a white state, but undergo a process of dyeing, softening, "stoking," &c., before being cut up into gloves.

The tanning of one average-sized skin requires about 1½ lbs. of good Sicilian sumach; but for leather which is to receive a bright scarlet dye, from one half to three quarters of a pound of gall-nuts are employed in preference. Inferior goat skins are tanned with a willow bark infusion, in pits, in which they are turned repeatedly, and laid out to drain, as in tanning sole leather. The finest skins for the brightest scarlet are cured with salt, to prevent their receiving damage in the transport, and are dyed before being tanned. This method is practiced in Germany and France.

Leather of deer and sheep skins is prepared with oil, for the purpose of making breeches, &c., and for wash-leather, used in cleaning plate. After they are completely

washed, limed, and beamrd, as above described, they have their "grain"-surface removed, to give them greater softness and pliability. This removal of the grain is called "frizing," and it is done either with the round edge of a blunt knife, or with pumice-stone. After being freed from the lime by steeping in fermented bran-water, they are pressed as dry as may be, and are then impregnated with cod-oil, by beating with stocks in the trough of a kind of fulling mill. Previously to the application of the oil, they are usually beat for some time alone to open their substance. The oiled skins are stretched, hung up for some time in the air, then filled with oil as before—a process which is 8 or 9 times repeated. The oil is slowly and evenly poured upon the skins in the trough during the action of the beaters. One hundred skins usually take up in this way from two to three gallons of oil. The filled oil skins are thrown into large tubs, and left for some time to ferment, and thereby to combine more intimately with the oil. They are lastly subjected to a weak potash lye bath, to strip them of the loosely adhering oil. They are then hung up in the air to dry, and dressed for the market.—H. M.

LEATHER, RUSSIAN, as tanned at Kazan. The hides to be tanned may be either fresh from the animal or dry, no matter which; they are first laid to soak for 3 days and nights in a solution of potash, to which some quicklime is added. The potash used is made of the tree called in Russ *dim* (the common elm), which sort is said to be preferable to any other, if not essential; it is not purified, so that it is of a brown colour and of an earthy appearance; about 12 pounds of this (the pound is 36 lbs. English), and 2 pounds of lime, serve for 100 skins. As they have no way of ascertaining the degree of causticity of the alkali but by its effect upon the tongue, when they find it weak they let the skins lie longer in the solution.

When the skins are taken out of this solution they are carried to the river, and left under water for a day and a night.

Next a vedro of dog's dung is boiled in as much water as is enough to soak 50 skins, (the vedro is equal to 2096 English Imperial gallons) but in the winter time, when the dung is frozen, twice that quantity is found necessary. The skins are put into this solution, not while it is boiling hot, but when at the heat which the hand can bear; in this they lie one day and one night.

The skins are then sewed up so as to leave no hole; in short, so as to be water-tight; about one third of what the skin will contain is then filled up with the leaves and small twigs chopped together of the plant called in Russ *Toloknanka* (*Aribulus uva-ursi*, sometimes called bear berry), which is brought from the environs of Solikamskaya, and the skin is then filled up with water.

The skins thus filled are laid one on the other in a large trough, and heavy stones upon them, so as by their weight to press the infusion through the pores of the skin in about 4 hours; yet, as it was said at the same time, that the skins are filled up with the same water which had been pressed out 10 times successively, and that the whole operation takes but one day and one night, this leaves but 2½ hours for each time.

The skins are then taken to the river and washed, and are ready for the dyeing. The whitest skins are laid aside for the red and yellow leather.

(The operations in dyeing follow, but are here omitted.)

To soften the skins after dyeing, they are harassed by a knife, the point of which is curved upwards.—H. M.

LEATHER, CURRYING OF. The currier's shop has no resemblance to the premises of the tanner, the tools and manipulations being quite different.

Within the last twenty or thirty years, many tanners have added the currying business to their establishments, and many-curriers have likewise commenced tanning; but in each case, an extension of premises is necessary, and the two departments are still separate. The advantage derivable from this arrangement are two-fold.—first, a saving of time is effected, for as the tanned leather is sold by weight, it is required to be well dried before being disposed of to the currier, an operation which is not needed where the tanner carries on the currying also; and secondly, by the currier's art, the skins can be reduced to a comparatively uniform thickness previous to their being tanned, thus saving time and *bark* (used for tanning), and insuring a more equal distribution of tannin through the substance of the skin. In the following description, the business of currying will be considered as practised at the present time.

The currier's shop or premises, to be convenient, should be spacious. A frequent, though not universal method, is to have the ground-floor appropriated to such operations as require the use of a large quantity of water. The place or apartment thus used, is called the *scouring-house*, and is commonly furnished with a number of *ruts* or *casks open at one end*, in which the leather is placed for the purpose of soaking, and undergoing such treatment as will be hereafter describ'd. In this apartment also is placed a large, flat, slate stone, called a *scouring-stone*, or, more consistently, the

stones on which the leather is scoured. This stone, which has its face perfectly flat and smooth, and which should measure 8 or 9 feet in length, by $4\frac{1}{2}$ broad, forms a table, supported generally by masonry, but sometimes by a strong frame of wood, so constructed, that the water, which is freely used in scouring, may drain off on the opposite side from that on which the workman is engaged; an inclination of about three or four inches on the width of the table, is sufficient for this purpose. Another piece of furniture very frequently found in, or on the same floor with the scouring-house, is a block of sandstone, in the form of a parallelopipedon, between 2 and 3 feet long, and 9 or 10 inches broad, the upper face of which is kept as near as possible a perfect plane; this stone is fixed at a convenient height on a strong trussel, and is called the *rub-stone*, because here the workman rubs or sharpens his knives and other tools. In some large establishments where the premises and water are heated by steam, the scouring-house will be found with a service of pipe leading to the various vats, and the boiler, for generating the steam, may be conveniently placed in or near this part of the building.

The floor above the scouring-house, in the arrangement here laid down, is what is specially designated the *shop*. The furniture in this department consists of a beam, (fig. 1112) on which the leather is shaved. It consists of a heavy block of wood, on which the workman stands, and into one end of which a stiff piece of wood is firmly mortised, at an angle of about 85° ; this upright (so called) is about a foot wide, the height being greater or less, according to the height of the workman, each of whom has his beam adjusted to meet his convenience. On the front of the upright, a piece of deal is firmly screwed, to which is glued a face or plate of *lignum vite*, worked to perfect smoothness to agree with the edge of the knife used in the operation of shaving. It is of the greatest importance to the workman, to keep his skin from injury, that his knife and beam should be kept in good order. A table or tables, generally of mahogany, large planks of which are used for the purpose to avoid joints, may be said to form a necessary part of the furniture of this department. These tables are firmly fixed, to resist the pressure of the workman when using various tools; and as light is of the greatest consequence in the operations performed on them, they are usually placed so as to have windows in front of them. A high trussel is frequently used, across which the leather is thrown, after undergoing any of the processes, while the currier subjects other pieces to the same operation.

Another part of the premises is termed the *drying loft*. In good buildings the drying loft is surrounded with *weather boards*, constructed to be opened or closed as may be required. The use of this part being the drying of the leather, the ceiling is furnished with a number of rails or long pieces of wood, with hooks or nails on which to hang the leather for drying, and where steam is used for this purpose, the floor is traversed with pipes for heating the loft. Here also is a table, similar to that previously described; it should not be less than 7 or 8 feet long by $4\frac{1}{2}$ broad, if possible, without joint, and with a smooth face.

There are other subordinate departments, each furnished with a table similar to those described.

Of the tools used in currying, the knife stands first in importance (fig. 1113). Here *a* and *b* are two handles, *a* is held in the left hand, and forms a powerful lever when the edge *c* is applied to the leather. The blade of the currier's knife is peculiarly tempered; it is composed of a plate of fine steel, strongly riveted between two plates of iron. This instrument is taken to the *rub stone*, and ground to a perfectly sharp edge by successively rubbing forward and backward, care being taken to keep the edge true, that is, straight. When this has been satisfactorily accomplished, it is still further rubbed on a fine Scotch or Welsh stone called a *clearing-stone*, until the scratches of the *rub-stone* disappear.

In this operation a fine thread or wire forms on the edges, for the knife has two edges (*cc*) which must be carefully got rid of; after which it is wiped dry, and the edges greased with tallow or oil. The workman then takes a strong steel, and placing himself on his knees, he fixes the straight handle *b* against any firm body, and the cross handle *a* between his knees; then holding the steel in both hands

be carefully rubb'd forward and backward the whole length of the edge. During this operation the knife is gradually raised by means of the handle *a*, until it is nearly perpendicular; by this means the edge is turned completely over. If the knife is not well tempered, the edge thus obtained will be irregular, or broken; in either of which cases it is of no use whatever.

To keep the instrument just described in proper order requires great skill on the part of the currier. The edge is so delicate and liable to injury that it cannot be used

1114

more than a minute or two without losing its keenness. To restore this a very carefully prepared small steel is used, *fig. 1114*; the point of the steel is first run along the groove which is formed by turning the edge over, and the steel is then made to pass outside the edge (*fig. 1210*). It is remarkable that a skilful hand can thus restore the efficiency of the knife, and keep it in work for hours without going for a new edge to the *rub-stone*. The other tools will be described as their uses are mentioned.

The first thing done by the currier is the soaking of the leather received from the tanner in water; the skin requires a thorough wetting, but not to saturation. In some cases the thicker parts are partially soaked before the immersion of the whole, and when from the nature of the skin this cannot be done, water is ap-

1116

1115

1117

plied to the stout parts after the dipping; it is requisite that the whole should be as near as possible equally wet. In some instances the wetted leather is beaten, and sometimes a coarse graining-board (hereafter to be described) is used, to make it more supple previous to shaving it. The skin is then laid over the beam (*fig. 1116*) and the rough fleshy portion is shaved off. This operation is generally called *shaving*. In all the operations at the *beam* the leather is kept in its place by pressure of the knees or body of the workman from behind. In *shaving* the right hand handle of the knife somewhat precedes the left, but in *shaving*, properly so called, the left hand precedes the right, *fig. 1117*. In *shaving* the knife is driven obliquely a few inches at a time, in shaving it is driven with great force, not infrequently from the top to the bottom of the beam; great skill is requisite in the performance of these operations, to guide the knife and to keep its edge. The carpenter's plane can be most completely regulated by the projection of the plane iron from the wood, but the currier's knife admits of no such arrangement, and the unskilful currier is constantly liable to injure the leather by cutting through it, as well as by failing to produce a regular substance. The

kind of skin, and the use for which it is designed will regulate the work at the beam. In some cases, as in the calf-skin, it is skived and then shaved, or, (as it is called) *flattened* at right angles to the skiving — in other kinds, as the cow-hide prepared for the upper leather of heavy shoes, after skiving it is *skaved across* (i. e. nearly at right angles to the skiving), and *flattened* by being again shaved in the same direction as the skiving. In some manufactories there are certain kinds of leather which are subjected to the operation called by carriers *stomung*, before *flattening*; this is done by forcibly driving the *stock-stone* (fig. 1115) over the grain side of the leather, thereby stretching it, and rendering the grain smooth. The *flattening* process is considerably facilitated by this stomung, and the skin has been allowed slightly to harden by exposure to air, and the edge of the knife is fine, as it should be, the workman has but to strike the flat part of the knife over the leather after the shaving is performed, to produce a beautiful face to the flesh side of the skin. It will not be difficult to understand that

1115

1119

a good hand is easily distinguished from an inferior one in this part of the business. With such nicety and a skilful workman set the edge of his knife, that although there seems nothing to guide him, he can take shaving after shaving from the hide extending from the top to the bottom of the beam, thus rendering the leather extremely even in its substance.

After the process of shaving is completed, the leather is placed in water, where it remains until it is convenient to carry on the operation next required. It is to be observed that in the condition in which leather is shaved, it cannot long be kept without becoming heated; when, however, it is put into water, it is safe from injury, and may be kept a very long time, provided the water be occasionally changed for a fresh, sweet supply; stale water is regarded as injurious for the skin to remain in.

Scouring is next proceeded with; the skin is taken out of the water, and laid on the scouring-stone. In respectable manufactories, it is usual first to *scour on the flesh*; this is done by passing a *slicker* smartly over the flesh side, by which the *grain* of the leather is brought into close contact with the scouring-stone, and, being in a wet condition, the air is easily excluded, so that the leather *sticks* to the stone. A plentiful supply of water is now applied, and a large brush, with stiff hairs, is rubbed over the flesh, or upper side. Portions of the surface, in a pulpy condition, come off with the scrubbing, and the skin presents a soft, whitened, pulpy appearance; the pores are rendered capable of containing more moisture, and, altogether, the leather is much benefited. The *slicker* is a plate of iron or steel, or for particular purposes, of brass or copper; it is about five inches long, and like the *stock-stone*, is fixed in a stock, or handle (fig. 1119). It is sharpened at the *rub-stone*, by grinding the plate perpendicularly, and then on either side, thus producing two edges (or rather, right angles). The edges thus produced are not of an order to cut the leather, but rather to *scrape* it. The *slicker* is not intended to remove irregularities in the leather but its uses are various, and it may be considered a very important tool as will hereafter appear.

In the process of *tanning* the grain side of the hide or skin becomes covered with a whitish body, derived from the bark called *blom*; this is more or less difficult to remove according to the hardness or softness of the water used in tanning, and the peculiar treatment of the tanner. It is, however, the carrier's business to remove it, which he effects thus:—In the case of leather, whose grain is *tender*, as *cordovan*, which is manufactured from horse hides, the grain being kept uppermost, the leather is spread on the scouring-stone, and being plentifully supplied with water, is stretched by using the *slicker*, or a fine pebble, ground to the shape of the *stock-stone*, the *blom* is thus loosened, and, at the same time, by making it adhere to the scouring-stone, the next operation is readily carried on, which consists in smartly brushing the grain with a stiff-haired brush, at the same time keeping a quantity of water on the surface, the *slicker* is again used to remove the water and loosened *blom*, and the scouring is complete. In the scouring of calf-skins, and cow or ox hides, the *stock-stone* is used to fix the leather, and a piece of pumice-stone, the face of which has been ground to smoothness, and afterwards cut in grooves, is then forcibly rubbed over the grain, in order to remove the *blom*. In this, as in other operations, on the scouring-stone, water is a necessary ingredient. The *blom* being sufficiently loosened by the pumice-stone, the brush is used to scrub up the remaining dirt, which is then

removed by the stock-stone or slicker. In harness leather, which is stout, and requires to be stretched as much as possible, the pumice-stone is seldom used, the stock-stone and scouring-brush being lustily applied until the bloom is sufficiently removed. Ordinary manufacturers within the present (nineteenth) century, have considered the operations of the scouring-house complete at this point. The modern currier takes a different view, and not unfrequently detains his *scoured* property for days, and sometimes for weeks in the *scouring-house*.

If the leather is imperfectly tanned, or it is required to be made of a bright colour, there are other processes to be passed through. In these cases sumach (an evergreen shrub of the natural order *Anacardiaceæ*, genus *Rhus*, and from the bark of which all the leather made in Turkey is said to be tanned) is infused in boiling water, and when cooled to a tepid state the leather is placed in it. After staying a sufficient time it is taken to the scouring-stone; if *corduan*, it is slicked as dry as can be well accomplished on the *flesh* side; other leather is for the most part slicked in a similar way on the grain side. Saddle leather which is required to be of a bright colour is still farther placed in warm water slightly acidulated with sulphuric or oxalic acid, or both; here for a time it is kept in motion, then taken to the scouring-stone, it is washed with peculiar chemical lotions, according to the taste or knowledge of the workman; then again it is dipped in tepid sumach infusion, then slicked with a copper or brass slicker (iron is liable to stain leather thus prepared), and a thin coat of oil being applied to either side it is removed to the *drying-loft*. Until within a very few years, much time and trouble were taken to produce *very bright* leather for the saddler; but of late, brown-coloured leather has been adopted to a considerable extent, as it is less liable to become soiled. Nearly all leather is placed a short time in the *loft* before farther manipulations are carried on, in order to harden it slightly by drying.

In the drying loft, or its immediate vicinity, the leather receives the *dubbing* (*dubbing*, probably) or *stuffing*. The substance so called is composed of tallow brought to a soft plastic condition by being melted and mixed with *cod-liver oil*; occasionally *wal* (an oil made in preparing sheep skins) is in very small quantities added to the mixture. This is laid upon the leather either with a soft haired brush or a mop made generally of rags.

The leather is prepared for *stuffing* by wetting slightly such parts as have become too dry. It is then taken to the table previously described, which being slightly oiled the process is carried on by placing the skin on the table in the manner most convenient for stretching it and making the surface smooth. In those kinds that have a rough wrinkled grain the *flesh* side is placed next the table and the *stock-stone* is used very smartly to stretch and smooth the grain. A kind of *clump* or *holdfast*, composed of two cheeks fastened with a screw, is sometimes used to prevent the leather from moving during this operation, but in general these are not required; the slicker is then applied to remove the marks left by the *stock-stone*, and a thin *stuffing* being spread over the grain it is turned over, slicked on the *flesh* lightly, a coat of *stuffing* is spread over it, and it is hung up to dry. In those kinds which have to be blacked (or stained) on the grain, a little *cod oil* only is spread on the grain, and the slicker is applied on the *flesh* side most laboriously previous to *stuffing*. Much skill is required to give the requisite quantity of *stuff* (*dubbing*) to the leather without excess, excess being injurious, and the quantity required is farther regulated by the freshness or otherwise of the leather, the tan-yard from which it comes, and the treatment it has received in the *scouring-house*.

When dry, the skins or hides are folded together, to remain until required. It is certain the leather improves by remaining some weeks in this condition. It should be observed that, in drying, the leather absorbs a large quantity of the oleaginous matter with which it is charged, and the unabsorbed portion forms a thick coating of hardened greasy matter on the *flesh* side.

Leather which has to be blackened on the *flesh* (*wax leather*), from this point, receives different treatment from grain leather. *Wax leather* is taken to the *shup-side* and softened with a *graining-board*. The skin is laid on the table and doubled,

1121

1120

grain to grain, the *graining-board* (fig. 1121), which is confined to the hand by a leather strap (a), is driven forward and drawn back alternately until a grain is raised on the

leather, and it has attained the required suppleness. Observe, the graining-board is slightly rounded on the lower surface, and traversed by parallel grooves from side to side, which are coarser or finer, as occasion requires. The grease is next removed from the flesh by the slicker, and afterwards a sharp slicker is passed over the grain to remove grease or other accumulations from it. The next process is called *whitening*. The leather is laid over the *beam*, and a *knife* with an extremely fine edge is used to take a thin shaving from the flesh side; this is a point at which a currier's skill is tested. The knife used is one that has been very much worn, the quality of which has been tested to the utmost; and so extremely true is the edge expected, that not the slightest mark (*scratch*) is allowed to appear on the surface of the leather. Only a good workman can satisfactorily accomplish this. The slightest gravel in the flesh of the skin may break the edge of the knife in pieces, and it is not easy to rectify so serious a misfortune; besides, a poor workman may tear up the edge by *steeling*, an operation which ought to mend the mischief instead of provoking it.

A fine *graining-board* is next used to soften the leather; the stiffer parts being *boarded* both on the grain and flesh sides, and the operation being carried on in two or three directions, to insure both softness and regularity of grain. *Flouring* is performed by doubling the leather and driving the double part forward and drawing it back by the graining-board.

The leather is now prepared for the *waxer*, and passes, consequently, into his hands. Waxing, in large establishments, is a branch considered separate from the general business, and is usually in the hands of a person who confines himself to this occupation alone. The skin is laid on a table and the *colour* rubbed into the flesh side with a brush. It is necessary to give the brush a kind of circular motion to ensure the required blackness in the leather. The *colour* is made by stirring a quantity of the best lampblack into *cod-liver oil*; sometimes a little *dabbing* is added, and in order to make it work smoothly so as not to clog the brush, some stale *tan water* from the vat in the scouring house is *beaten* up with the mixture until it combines therewith. The preparation of the *colour* is an important affair, and requires a considerable amount of time and labour to render it such as the *waxer* desires.

A *slick-stone*, or *glass*, is next used; this tool is about the size and shape of the slicker, but instead of being ground like it, the edges are very carefully removed, so that while, from end to end, it preserves nearly a right line, it is circular across the edge. The *stone* (a fine pebble) is little used now, plate-glass being substituted for it. The use of the tool just described is to smooth the flesh after the operation by the colouring brush, thereby getting rid of any marks made on the surface.

The next step in waxing is what is called *sizing*. Size is prepared by boiling glue in water—the melted glue is diluted with water to the extent required—in some cases it is softened by mixing *cod-liver oil* with it in cooling. When cold, it is beaten up with various ingredients, according to the taste or experience of the *waxer*; the *waxer* then well rubs the size into the coloured side of the leather, and with a sponge, or, more generally, the fleshy part of his hand, smooths it off. When dry, the *slick-stone*, or *glass*, is again applied, thus producing a polish on the size; and a very thin coat of oil completes the work. In different manufactories different methods are pursued, but the above is convenient and satisfactory in almost all circumstances. It is now ready for the shoemaker.

Leather intended to be blacked on the grain, is left folded up when dry after stuffing. Some years ago it was the custom to stain these kinds of leather, while wet in the scouring-house, by spreading stale urine over it and then applying a solution of *copperas* (sulphate of iron). That method is now exploded. The dry skins or pieces of leather are laid on the shop-board; a brush is used to saturate the grain with urine, or so is now more common, a solution of soda in water, and a peculiar preparation of iron is afterwards laid over it, which blackens the surface. It may be observed that in wax-leather a body of black is laid on, and rubbed into the flesh; in grain leather the black is a stain. After the blackening, it is necessary to rub a small quantity of oil or *dabbing* over the blackened surface, then turning the oiled grain toward the table, a sharp slicker is used on the flesh side; the leather sticks to the table by means of the oil, and the slicker is driven so smartly over it, that it is *stretched* on the table, at the same time that the grease is removed. It is quite an important point to take *all the stretch* out of the leather in this operation, after which it is turned over; the flesh is covered with a very thin coat of hard tallow, a roll of tallow being rubbed over the table, for the purpose of keeping the leather fastened to it. A dull slicker is used on the grain to remove remaining marks and wrinkles, or to smooth any coarse appearance on the grain; a sharp slicker removes all the grease, and a thin coat of weak size, made of glue dissolved in water, is spread over it and the process, usually called *seasoning*, is completed. The next object is carefully to dry the *seasoned* leather, and in this state it may be stored without injury.

The next step is very similar to that described in the case of *raw leather*, and called *whitening*:—it is then softened by means of a fine graining-board, or a board of the same shape and size covered with cork, the grain side is placed next the table, and the flesh doubled against the flesh, and thus driven forward and back ward until the required degree of suppleness is obtained. The loose particles of flesh are brushed off and a slicker carefully passed over the grain removes all marks of the last operation. If a sufficiency of stuff has not been applied in the drying-loft, the deficiency is remedied by a coat of *tallow-dubbing* now spread over the grain and allowed to remain some hours. As the leather absorbs the oily matter a hardened coat of grease has to be removed by the aid of the slicker. The leather is then sized, and a very thin coat of oil spread over the size, completes the operation.

In the preparation of various kinds of leather, or of leather for particular purposes, the currier has particular appliances. Harness leather is considerably dryer than other kinds before stuffing, and is subjected to immense labour by the stock-stone and slicker, to procure a smooth grain. It is blackened when dry like other grain leather, but instead of the oiling and other processes described, the hardest tallow procurable is rubbed into it, *stained* with a fine pebble, slicked, and tallow again rubbed into it by the hand. When dry after this operation, the grease is slicked from the flesh side, and a repetition of the tallowing, stoning, and rubbing finishes the work.

Saddle leather, which is cut into comparatively small pieces, after hardening in the drying loft, is passed through a very different process from any described previously. The skin of the hog is much used for certain parts of hackney saddles, and the bristles, when removed by the tanner, leave indentations, or even holes in the tanned skin. Probably it was deemed desirable to obtain some imitation for the parts of the saddle where the hog skin was not suitable. The skin of the dog-fish (*Squalium*, Cuv.), to some extent supplied the imitation, having hard tubercles on its surface. At first the skin was laid on the leather and lustily pressed into it by rubbing it with a pebble or plate of glass; at length a press was invented, and more recently various methods have been proposed to produce the best effect. We have here (fig. 1122) a

1122

representation of one of these presses, which may stand as a type of all others: *a a* are the feet into which the uprights are inserted; *b b* are the two upright sides tied at the top by *c*, a similar cross piece ties them a little above the feet; *d* is a leaf fastened with hinges, which closes upon *c* when the press is not in use; *e e* are screws which press off the iron plate, in which the axes of the rollers *f f* are inserted. These plates imbedded in the uprights *b b* have considerable play, so as to allow the rollers *f f*

more or less pressure as the case may require. The dotted line *i i'*, represents an iron bar or cylinder, supplied with a small cog wheel at *i'*, and a *crank-handle j*, this is turned round by the hand, and the small cog wheel acts on a larger one *k*, which is attached to the axis of the roller *f*. *f* is a solid roller of hard wood, such as *lynum vite*; upon this cylinder is strongly glued the *fish skin*, previously alluded to; *h* is a cylindrical solid piece of wood covered with stout flannel; *l* is a piece of leather on which the leather to be pressed is placed; when all is adjusted the piece to be pressed is placed on *h*, the handle is moved slowly round, and the whole is carried between the rollers; the leather thus receives the imprint of the *fish skin*, and at the same time becomes extremely soft. After drying, this is fit for the saddler.

Of late years the currier has undertaken an office which was previously the business of the boot maker; namely, the *blocking* of boot fronts. This is performed by the instrument represented by *fig. 1123*. The leather is first dressed, as previously

1123

described, up to the point of being ready for *whitening*. The fronts are then cut (*fig. 1123 a*), and when folded or doctiled appear as *fig. 1123 b*. 1' 1', 1 1, is a strong frame-work; 2, represents a pair of cheeks, strongly fastened in the frame, and regulated as to distance by a screw, these cheeks are lined with zinc; 3 is a strong plate of metal, the angle at 3 corresponding exactly with the angle of the cheeks; the ends of this plate are fixed in movable plates passing down the columns 1' 1'; 4 is a handle by which the instrument is worked, and which by cog-wheels acting on the movable plates brings 3 downwards. The front, *a*, is laid, after a thorough soaking in water,

over the check 2, the handle being turned, it comes down upon the front, and forces it through the small opening between the checks, and when brought out below the checks, it has the appearance here given (fig. 1124). The piece 3 having passed the front between the checks, is removed (lower), and the weight 3 comes in bringing the perpendicular movable plate in their place, when 3 is again put in position, and thus the operation is rapidly carried on. After this the fronts are regularly placed on a block, being bound into position by an instrument called the *flange* (fig. 1124) and held in their place, after this they are slightly dried and

1124

dried. Some ingenious methods have been adopted for softening the fronts, so as not to disturb the blocking. They are whitened on a very sloping beam (fig. 1125), which enables the workman to hold them better than he could on the common beam. They

1125

are again blocked by the water, and when these processes are carefully performed, much trouble is saved to the boot-maker. Of course, in a manufactory many appliances are found which are not here mentioned; the general idea, however, may be easily gathered from this description. The work is dirty and very laborious, requiring great skill and experience, and consequently good workmen have generally commanded better wages than other mechanics.

It has intended for covering coaches are shaved as thin as shoe blades, and blocked on the grain.—H. M.

LEATHER SPLITTING. This operation is employed sometimes upon certain sorts of leather for gloves, for bookbinders, shoemakers, and always to give a uniform thickness to the leather destined for the seats and wheel-carriage seats.

Figs 1126, 1127, 1128, 1129 represent a well constructed machine for that purpose, of which *fig. 1126* shows the front view, *fig. 1127* a view from the left side, *fig. 1128* a ground plan, and *fig. 1129* a vertical section across the machine. *a* is a strong table, furnished with four legs *b*, which to the right and left hand bears two horizontal pieces *c*.

1126

Each of these pieces is cut out in front, so as to form in its substance a half-round fork, that receives a cylinder *d*, carrying on its end a toothed spur-wheel *e*. Motion is communicated to the wheel by means of the handle *f*, upon whose axis the pinion *i* is fixed,

1128

1127

working into the wheel *d*, made fast to the end of the cylinder round which the leather is rolled. The leather is fixed at one of its ends or edges to the cylinder, either with a wedge pressed into a groove, or by a movable *againe* of the cylinder itself.

The table, *a*, is cut out lengthwise with a slot, that is widened below, as shown in *fig. 1128*.

The knife *k* (*figs. 1128* and *1129*) is fixed flat upon the table with screw bolts, whose heads are countersunk into the table, and secured with taps beneath (*fig. 1129*), the edge of the knife being placed horizontally over the opening, and parallel with it.

In *fig. 1128* the leather, *l*, is shown advancing against the knife, getting split, and has a portion curled round the cylinder, which is made to revolve in proportion as the leather is cleft. The upper portion of the leather is rolled upon the cylinder *d*, while the under half, *l*, falls through the oblong opening upon the ground.

In regulating the thickness of the split leather, the two supports, *m*, act; they are made fast to the table (one on each side of the knife), and are mortised into the table by two *againes* secured beneath. These supports are furnished near their tops with keyed slots, by means of which the horizontal iron rod *o* (*figs. 1128*, *1129*) is secured,

and the end of the uprights they press upon the springs *p p*, which tend to raise the *rod o* in its two end slots; but the adjusting screws *q*, which pass down through the tops of the

supports into the mortise *n* (fig. 1128), and press upon the upper half of the divided table, counteract the springs, and accordingly keep the rod *o* exactly at any desired height or level. The main rod *o* carries another iron bar, *r*, beneath it, parallel and also rectangular, fig. 1128. This lower bar, which is rounded at its under face, lies upon and presses the leather by the action of two screws, which pass through two upright pieces (figs. 1126 and 1128) made fast to the table; thus the iron bar *r* may be made to press forwards the edge of the knife, and it may be adjusted in its degree of pressure, according to the desired thickness of the leaf of split leather that passes through under it.

Fig. 1129 shows that the slant or obliquity of the knife is directed downwards, over one of the edges of the oblong opening *g*; the other edge of this opening is provided with an iron plate *t* (figs. 1128, 1129), which serves to guide the blade in cutting the leather to the proper depth. For this purpose the plate is made adjustable by means of the four springs *u* (fig. 1129) let into the table, which press it downwards. Four screws, *v*, pass down through the table, each belonging to its respective spring *u*, and by means of these screws the plate *t* may be raised in any desired degree. Each of the screws *v* has besides a small rectangular notch through which a screw bolt *x* passes, by which the spring is made fast to the table. Thus also the plate *t* may be made to approach to or recede from the knife.

y, in figs. 1126 and 1128, is a flat board, laid upon the leather a little behind the edge of the plate *t*; this board is pressed by the cylinder *z*, that lies upon it, and whose tenons rest in mortises cut out in the two supports *a'*. The cylinder *z* is held in its position by a wedge or plate *b* (figs. 1126 and 1127), which passes through the supports. When the leather has been split, these pins are removed, and the cylinder rises then by means of two counter-weights, not shown in the figures.

The operation of the machine is as follows:—The edge or end of the leather being secured to the cylinder *d*, the leather itself having the direction upon the table shown in fig. 1124, and the bar *r* in its proper position over the knife, the edge begins to enter in this position into the leather, while the cylinder *d* is moved by the handle or winch, and the piece gets split betwixt the blade and the roller *d*. When the other end of the leather, *A*, advances to the knife, there is, consequently, one half of the leather split; the skin is to be then rolled off the cylinder *d*; it is turned; the already split half, or the end of the leather, *A*, is made fast into the wood of the cylinder, and the other half is next split; while the knife now acts from below, in an opposite direction to what it did at first.

That the unrolling of the leather from the cylinder, *d*, may not be obstructed by the pinion *i*, the stop-wedge *e* (figs. 1125, 1127) is removed from the teeth. In the process of splitting, the grain side of the leather is uppermost, and is therefore cut of an uniform thickness, but the under side varies in thickness with the inequality of the skin.

Several other ingenious contrivances have been introduced for this purpose, illustrated descriptions of which have been given by Herbert, who states that a splitting-machine, long used by the Messrs. Bevington, of Bermondsey, had been made to split sheepskins into three equal parts, one of which, that on the grain side, might be used as leather; the middle portion converted into parchment; and the slice on the flesh side, being unequal in thickness, and therefore unfit for any better use, being used for glue making. In this machine the skin is drawn between two revolving rollers, and presented, as it emerges from their grasp, to the edge of a long and very sharp knife, which is kept continually moving a little backwards and forwards with great velocity. As a skin of unequal thickness could not be grasped in the proper manner between two

perfectly true and rigid rollers, the upper roller, instead of being solid, is composed of a number of circular discs or rings of metal, about half an inch thick, slipped on to an axis rather smaller than the holes in their centres, but compelled to revolve with it by means of what may be termed a planetary axis, which is a rod passing loosely through holes in the whole series of discs, between their centre and their circumference, and so connected with the axis by its ends as to be carried round with it. By this contrivance the upper roller is enabled to adapt its surface to that of the skin, which is everywhere pressed with an equal force, due to the weight of the discs of which the upper roller is composed. It is stated in the *Frany Magazine* "that this machine will split a sheepskin of the ordinary size in about two minutes, during which time the knife makes from two to three thousand vibratory motions to and fro." This machine is said to be the invention of Lieutenant Parr. Another contrivance is known as Duxbury's Patent Skin Splitting Machine, in which the knife consists of a series of plates of steel, so attached to the periphery of a wheel or disc, seventeen feet in diameter, as to form a gigantic cutting instrument, resembling a crown or trepan saw, the compound blade projecting horizontally from the rim of the wheel parallel to its axis. The skin to be split passes round the circumference of a horizontal drum, the axis of which is at right angles with that of the great disc, and lies very nearly in the same plane with its face, and which instead of being perfectly cylindrical has its sides so hollowed as to present a concavity perfectly tallying with the curvature of the periphery of the disc. As therefore the drum revolves it brings the skin, which is confined closely to its concave surface by a contrivance somewhat resembling the upper roller in the machine above described, in contact with the edge of the revolving knife, which cuts by a continuous onward movement, instead of a sawing action backwards and forwards. The extreme nicety required to fix the concavity of the feeding roller to the edge of the circular knife, and to keep the knife or cutter itself perfectly true in shape, appear to be the chief objections to this ingenious contrivance.—*Frany. Cy., Suppl., Leather.*

Exports of Leather of British Produce and Manufacture in 1850 and 1851:—

		Quantities		Declared Value	
		1850.	1851.	1850.	1851.

II 31.

LEATHER, VEGETABLE. Under this name a new material, composed of India rubber spread upon linen, has been introduced. Of this the *Mechanics' Magazine*

writes :—" Having seen some specimens of these leathers, as well as various articles of utility manufactured therewith, we have been induced to pay the extensive works of Messrs. Spill and Co., the eminent & ever-greent contractors, on Stepney-green, a visit, in order to cull sufficient to place upon record the present position of artificial as a substitute for real leather. The face and general character of the vegetable leather resembles the natural product so closely, that it is only by actual examination that the difference can be determined. This is more particularly the case in that description which is made for bookbinding, the covering of library tables, and like purposes. Amongst other advantages it possesses over leather proper, may be mentioned, that however thin the imitation is, it will not tear without considerable force is exercised; that it resists all damp, and that moisture may be left upon it for any period without injury, consequently, it does not sicken or cockle, is always dry, and its polish is rather increased than diminished by friction. Add to these facts, that any attempt to scratch or raise its surface with the nail, or by contact with any ordinary substance, will not abrade it, and enough will have been said to justify its entering the list against an article of daily use, which has of late years been deemed far from sufficient for the demand, and has consequently risen in price to the manifest loss and injury of every class of the community. We believe that the largest entire piece of real leather that can be cut from a bullock's hide, is not more than 7 feet by 5 feet, and this includes the stomach and other inferior parts. Vegetable leather on the contrary, is now produced 50 yards in length, and $1\frac{1}{2}$ yard wide, every portion being of equal and of any required thickness, and the smallest portion is convertible. We were agreeably disappointed, however, to find that instead of vegetable leather being a discovery requiring the aid of ourselves and contemporaries, it was, although so young, an active agent in the fabrication of numerous articles of daily requirement, and that it had already become the subject of large, indeed we may say enormous, contracts. Caoutchouc and naphtha are used in its manufacture; but by a process known to the senior of the firm, who is himself an accomplished chemist, all odour is removed from the naphtha, and the smell of vegetable leather is rendered thereby less in strength, if anything, than that of leather. The principal objects to which it is at present applied, although it is obvious it will take a wider range of usefulness than leather itself, are carriage and horse aprons, antipolopols, soldier's belts, booklets which pack flat, harness of every description, bookbinding, &c. For, the latter, its toughness, washable quality and resistance to stains, render it remarkably fitted. Its thickness, which may be varied to any extent, is obtained by additional backing of linen, &c., combined with the caoutchouc, and its strength is something marvellous, while in the all-important commercial view, it is but one third the price of leather. Many of the articles we were shown possessed the appearance of much elegance and finish; but it was curious to observe, that although most of them could be made without a stitch, and within the factory itself, a deference to the feelings of the workmen in the several trades has been shown by the firm, and the material is given out as ordinary leather, to undergo the process of the needle, which it submits to with a greater facility than its original prototype."

LEDUM PALUSTRE. This plant is employed in Russia to tan the skins of goats, calves, and sheep, into a reddish leather of an agreeable smell; as also in the preparation of the oil of birch, for making what is commonly called Russia leather.

LEIR. An arched building, forming an annealing furnace, in which glass is tempered or annealed.

LEGUMINE is the name of a vegeto-alkali supposed to exist in leguminous plants.

LEMNIAN EARTH. A yellowish-grey earth, obtained from Lemnos by the Greeks. It is very similar to fuller's earth.

LEMONS. The fruit of the *Citrus limonum*. Both the juice and the peel of the fruit are employed medicinally, and in the preparation of lemonade. The quantity of lemons employed cannot be ascertained from the Custom House returns, as they are reckoned together with oranges. See CITRIC ACID, and OILS, ESSENTIAL.

LENSES. (*Lentille*, Fr.; *Linsenglas*, Germ.) Lenses are transparent bodies, usually made of glass, which by their curvature either concentrate or disperse the rays of light. Lenses are of the following kinds. *Double convex*, having the same or a different degree of convexity on either side. *Plano convex*, having one plane and one convex surface. *Concavo convex*, having one concave and one convex side, commonly called *meniscus lenses*. *Plano concave*, having one plane surface and one concave one; and the *double concave lens*.

The first three, which are thicker in the middle than at the edge, are *converging lenses*, because they occasion the rays of light to converge in passing through them. The others which are thicker at the edge than in the middle, and therefore cause the pencils of light refracted through them to diverge, are called *diverging lenses*.

For the most complete examination of the laws regulating the construction of lenses, and the action of these on the rays of light we must refer the reader to Sir John

Herschel's admirable treatise on *Light* in the *Encyclopedia Metropolitana*. In this work we have only to deal with the mode of manufacturing the ordinary *lenticles*. The spherical surfaces are produced by grinding them in counterpart tools, or discs of metal, prepared to the same curvature as the lenses. For the formation of the grinding tools, a concave and a convex template are first made to the radius of the curvature of the required lens. The templates of large radius, are sometimes cut out of crown glass. More usually the templates are made out of sheet brass, the templates of long radii are cut with a strong radius bar and cutter, and those of only a few inches radius are cut in the turning lathe. The brass concave and convex gauges are cut at separate operations, as it is necessary to adjust the radius to compensate for the thickness of the cutter, and the brass templates are not usually corrected by grinding, as practically it is found more convenient to fit the tools themselves together. The templates having been made of the required radius, are used for the preparation of the grinding and polishing tools, which for concave lenses consist of a concave rough grinding tool of cast iron called a *shell*.

A pair of brass tools is however the most important part of the apparatus. (One of these is concave and the other convex, made exactly to the curvature of the templates and to fit each other as accurately as possible. The concave tool is used as the grinder for correcting the curvature of the lenses after they have been roughly figured in the concave shell, and the convex tool is employed for producing and maintaining the true form of the concave grinding tool itself, and also that of the polisher. These polishers are adjusted with great accuracy. The concave tool is placed upon the convex, and they are first rubbed together dry, so that by the brightened parts the inequalities may be distinguished, they are then ground true, first by means of emery and water, and then with dry emery.

The following figure (1130) represents these tools, which are fitted with screws at the back so that they can be fixed upon pillars, in connection with the machinery for giving motion to them.

By grinding with sundry varieties of motion which are required to produce the best effect, such as the production of motion which shall resemble as nearly as possible the kind of stroke which would be given by the hand, three tools are eventually brought to true spherical figures which fit each other exactly.

The glasses for lenses, being selected of suitable quality, they are brought to a circular form by means of flat pliers called *shanks*. The pressure of the pliers applied near the edges of the glass causes it to crumble away in small fragments, and this process, which is called *shanking* or *nibbling*, is continued until the glasses are made circular, and of a little larger diameter than the finished size of the lenses.

1130

A cement is made by mixing wood ashes with melted pitch. Some nicety is required in the adjustment of the proportion, since the cement must not be too adhesive nor must it be too hard or too brittle; generally about 4 lbs. of wood ashes to 14 lbs. of pitch are employed. This when melted is poured on one side of the glasses to be ground, in small quantities at a time, until a sufficient quantity adheres to the back of the lens to form a handle. The glass is rough ground by rubbing it within the spherical shell. The glass is rubbed with large circular strokes, and the shell is usually placed within a shallow tray to catch the loose emery or polishing powder which may be employed. When one side is rough ground in this way, the glass is warmed to detach it from the handle, which is transferred to the other side and the operation repeated. When both sides are thus rudely formed, the lenses are cemented upon a runner. The best object glasses for telescopes are ground and polished singly, while as many as four dozen of common spectacle glasses are ground and polished together. When many are thus fixed on one runner, the number must be such as will admit of their being arranged symmetrically around a central lens, as 7, 13, or 21, or sometimes 4 form the nucleus, and then the numbers run 14, 20. Lenses of ordinary quality are usually ground true and polished seven at a time. This runner with its lenses attached is shown in fig. 1131.

1131

The cement at the back of the lenses is first flattened with a heated iron. The cast iron runner is heated just sufficiently to melt the cement, and carefully placed upon the cemented backs of the lenses. As soon as the cement is sufficiently softened to adhere firmly to the runner, it is cooled with a wet sponge, as the cement must only be so far fused as to fill up the spaces nearly, but not quite, level with the surface of the lenses. The block of lenses is now mounted upon a post, and ground with the concave brass tool, fig. 1180, motion being given to it either by the hand or by

machinery applied to the grinding motion is already named. As the grinding process, the business of the emery powder employed is somewhat similar to the last operation, it is essentially the same to produce a semi-polished surface. The grinding being now pushed forward by the labourer, have to be polished. The polisher is done by warming a flat iron and setting it vibrating about one quarter of an inch thick with a mallet. A piece of thick wood in which is cut to the size of the polisher and secured to it, and placed in motion by working the handle with the foot. When this is properly adjusted it is covered with very finely divided emery powder, operated with a small wheel, and the polisher worked back and forth over the piece of the work with the same vibrating tool. Repeated supplies of emery powder is put in the polisher until it reaches quite level, and it is polished smooth with the tool. Many hours are expended in the proper preparation of a polisher. When completed it is placed upon the back of a horse and led to the post, and worked with wide and narrow strips and circles. When a very large number of planes are ground or polished at the same time, the power motion is assisted by the eccentric movement of a lever attached to the revolving shaft. In the processes of grinding and polishing, other materials besides emery and pumice powder are sometimes employed, such as sand, or cast-iron scales of iron, the finer kinds of which are much employed in the large iron manufacturing establishments.

Much more might be said on the subject of grinding and polishing lenses, but it is one of those processes of manufacture which scarcely come within the limits of the present work. Still it was thought to be of sufficient importance to receive some general notice. The grinding and polishing of the most varieties of lenses for telescopes, microscopes, and the like, require extremely nice manipulation. The best account of the processes and of the instruments used is now by the late Andrew Ross in the fifty-third volume of the *Transactions of the Society of Arts, London*, pp. 10. *Mechanical Manipulation* there is also some very excellent practical information. See LIGHTHOUSE; PHOTOMETRY.

LEPIDINE CHLORIDE. A volatile base, in contact with chlorine, found in mineral water and in the fluid produced by dissolving chlorides with perch. C. C. W.

LEUCITE. A mineral found in volcanic rocks, containing usually 16 to 20 of silica, 23 to 40 of alumina, and 21 to 25 of potash.

LEUCOLINE. A compound of CHLORINE, produced during the destructive distillation of coal. See COAL GAS.

LEUKOL. See CHIROL.

LEVEL (a mining term). An adit gallery or horizontal working in a mine.

LEVIGATION is the mechanical process whereby hard substances are reduced to a very fine powder.

LEWIS is the name of one kind of shears used in cropping wool with a comb.

LIAS. Under this term are comprehended the strata which intervene between the Trias, or New Red Series, and the Inferior Oolite. In the aggregate they form considerable thickness, and occupy a large area in this country, stretching in a northerly direction from the sea west of Lyme Regis, in Dorsetshire, to Redcar, on the coast of Yorkshire. The strata which compose the Liasic series consist, in the lower part, of compact argillaceous limestone, alternating with or forming layers in clay, to a provincial pronunciation of which word the name has probably owes its origin. This limestone forms the base of a thick deposit of blue clays and marls, which are overlaid by a series of sands and mudstone, called Marlstone; these in their turn, are separated from another mass of sands, which form the uppermost member of the group, by a stratum of clay, known as the Upper Lias Clay.

By the term lias, however, is ordinarily only understood the calcareous and argillaceous division, which constitutes the lower section of the entire formation.

In an economical point of view, it is of considerable value from its furnishing a useful and durable stone, both for building and paving; for the latter purpose it is particularly suited, not only from the large dimensions of the flags it affords, but on account of its occurrence in thin layers, which, in many cases, when required for rough purposes only, are used in the state in which they are taken from the quarry, without undergoing subsequent dressing. The lime furnished by the blue lias limestone, is also well known, and in great request, some of the beds possessing the valuable property of forming hydraulic mortars and cements, for manufacturing which it is collected from the shore and the sea cliffs at Charmouth, and largely quarried at Lyme Regis and the neighbourhood.

The clayey members of the lias furnish a poor and cold agricultural soil, which is chiefly devoted to pasture, but the land upon the marlstone is, on the contrary, of a very rich and fertile description, and constitutes a district, where it prevails, that is marked by the luxuriance of its crops, and the excellence of the cider it produces. In the upper part, it contains beds of ferruginous, brown, calcareous sandstone, which

is well fitted for use in the bright shades where it occurs. The sandstone is also very much of a ferruginous character, but in some parts it is a ferruginous sandstone, and is so to speak, a valuable ore of iron, as in the neighbourhood of Huddersfield, to which attention has lately been directed by Mr. Edward Hull, of the Geological Survey of Great Britain.

In the neighbourhood of the extensive sands of the upper part of the Mendips, the calcareous sands of the upper part of the Mendips are covered with a rich agricultural soil. Until recently, these sands were considered to form the base of the Mendips or Collyer series, but the researches of Dr. Wright, render it highly probable that they should, with more propriety, be classed with the Mendips, and rather than with the Collyer strata.

The same found at Cheltenham and other places in the neighbourhood of Bristol, and which has in consequence received the name of Cheltenham marble, and has also been called corn, or Cheltenham marble, from the curious delineations displayed upon polished surfaces of it, resembling trees, landscapes, &c., is a limestone from the lower part of the Mendips. H. W. R.

BICHLORIDE. Fuming lixivium or, is the bichloride of tin, prepared by dissolving the metal with the aid of heat in aqua regia, or by passing chlorine gas through a solution of muriatic acid in tin on which gas is absorbed, evaporating the solution, and allowing it to crystallise. The anhydrous bichloride is best prepared by mixing four parts of muriatic acid with one part of tin, previously amalgamated with just so much mercury as to render it pulverisable; and by distilling this mixture with a gentle heat. A colourless fluid, the dry bichloride of tin, or the fuming lixivium, comes over. When it is mixed with one third of its weight of water it becomes solid. The first bichloride of tin is used in printing. See CALICO-PRINTING.

LICHEN. A certain set of plants, composed chiefly of cellular tissue devoid of green vesicles, with the stems and leaves undistinguishable, are termed Thallophytes. They are of two kinds, the first admitting of two divisions:—

1. *Aerial thallophytes*, or such as are nourished through their whole surface by air water are *ALGAE*. *Aerial thallophytes* nourished through their whole surface by air are *LICHENS*.

2. *The lichens* nourished through their thallus (spawn or mycelium) by juices derived from the matrix are *FUNGI*.

Lichens are numerous, as *Ground liverwort*, *Cup moss*, *Tree liverwort*, used in Sweden as a substitute for hops in brewing; *Gyrophora* employed by the hunters in the arctic regions as an article of food, under the name of *tripe de roche*; *Hedera* moss, *Island moss*, much used in this country as a remedy for coughs, the Chinese *gopher wood* lichen, and some others.

The *Terrestrial lichens* are also numerous. They furnish four principal colours, brown, yellow, purple, and blue.

Gyrophora pustulata and *Stictis pulmaria* yield brown colours. The latter, with medulla of tin and cream of tartar, produces on silk a durable carmelite colour. (*Guillemot*)

Parmelia parietina and *Eccrinia vulpina* produce yellow, the yellow principle of the former being called *chryso-genic acid*, that of the latter *vulpinic acid*.

Rocella Lecanora, *Varicolaria*, &c. yield purple and blue colours. In this country arch and eadbeer, purple colours, are prepared. In Holland, a blue colour, *lithos*.

The following is a list (from *Perron*) of the principal lichens employed by British manufacturers of arch and eadbeer, with their commercial names:—

OF HEILA WEDDA.

Angola Orch. Ha weed (<i>R. fuciformis</i>).	
Malagassar " "	
Mauritius " "	
Canary " (<i>R. tinctoria</i>).	
Cape de Verd " "	
Azores " "	
Madeira " (ditto and <i>fuciformis</i>).	
South America, large and round (<i>R. tinctoria</i>).	
South America, small and flat (<i>R. fuciformis</i>).	
Cape of Good Hope (<i>R. hypomaculata</i>).	

Barbary (<i>M. gadore</i>) (<i>R. tinctoria</i>).	
Caribbean and Sardinian " "	

MOSS.

Tartareous (<i>Lecanora tartarea</i>).	
Postulatus (<i>Gyrophora pustulata</i>).	
Canary Rock (<i>Parmelia parietina</i>).	
Utricular.	
Sardinian.	
Norway Rock Moss.	

Dr. Schrebner, to whom we are much indebted for many important inquiries connected with the application of chemistry, has given the following table of the lichens:—

* The evidence to be derived from Dr. Wright in favour of the liassic origin of these sands is that of a purely natural origin; the most natural arrangement is to connect them rather with the liassic gneiss than with the lias.—H. W. R.

LICKNER'S BLUE. The Silicate of Cobalt and Potash.

LIGHT. (*Lumière*, Fr.; *Licht*, Germ.) The operation of light as an agent in the arts or manufactures has scarcely yet received attention. Sufficient evidence has however been collected to show that it is of the utmost importance in producing many of the remarkable changes in bodies which are desired in some cases as the result, but which, in others, are to be if possible avoided.

There is a very general misconception as to the power or principle to which certain phenomena, the result of exposure to sunshine, are to be referred. In general light is regarded as the principle in action, whereas frequently it has nothing whatever to do with the change. A few words therefore in explanation are necessary. The solar ray, commonly spoken of as light, contains in addition to its luminous power, caloric power, chemical power, and in all probability electrical power. (See ACTION.) These phenomena can be separated one from the other, and individually studied. All the photographic phenomena are dependent upon the chemical (caloric) power. Many of the peculiar changes which are effected in organic bodies are evidently due to light, and the phenomena which depend entirely on heat are well known.

Herschel has directed attention to some of the most striking phenomena of light, especially its action upon vegetable colours. As these have direct reference to the permanence of dyes, they are deserving of great attention. The following quotation from Sir John Herschel's paper "On the Chemical Action of the Rays of the Solar Spectrum, &c." will explain his views and give the character of the phenomena which he has studied. He writes—

"The evidence we have obtained by the foregoing experiments of the existence of chemical actions of very different and to a certain extent opposite characters at the opposite extremities (or rather as we ought to express it in the opposite regions) of the spectrum, will naturally give rise to many interesting speculations and conclusions, of which those I am about to state, will probably not be regarded as among the least so. We all know that colours of vegetable origin are usually considered to be destroyed and whitened by the continual action of light. The process, however, is too slow to be made the subject of any satisfactory series of experiments, and, in consequence, this subject, so interesting to the painter, the dyer, and the general artist, has been allowed to remain uninvestigated. As soon, however, as these evidences of a counterbalance of mutually opposing actions, in the elements of which the solar light consists, offered themselves to view, it occurred to me, as a reasonable subject of inquiry, whether this slow destruction of vegetable tints might not be due to the feeble amount of residual action outstanding after imperfect mutual compensation, in the ordinary way in which such colours are presented to light, i.e. to mixed rays. It appeared therefore to merit inquiry, whether such colours, subjected to the uncompensated action of the elementary rays of the spectrum, might not undergo changes differing both in kind and in degree which mixed light produces on them, and might not, moreover, by such changes indicate chemical properties in the rays themselves hitherto unknown.

"One of the most intense and beautiful of the vegetable blues is that yielded by the

binerals of the dark velvet variety of the common heartsease (*Viola tricolor*). It is best extracted by alcohol. The alcoholic tincture so obtained, after several days' keeping in a stoppered phial, loses its fine blue colour, and changes to a pallid brownish red, like that of port wine discoloured by age.

"When spread on paper it hardly tinges it at first, and might be supposed to have lost all colouring virtue, but that a few drops of very dilute sulphuric acid sprinkled over it, indicate by the beautiful and intense rose colour developed where they fall, the continued existence of the colouring principle. As the paper so moistened with the tincture dries, however, the original blue colour begins to appear, and when quite dry is full and rich. The tincture by long keeping loses this quality, and does not seem capable of being restored. But the paper preserves its colour well, and is even rather remarkable among vegetable colours for its permanence in the dark or in common daylight.

"A paper so tinged of a very fine and full blue colour, was exposed to the solar spectrum concentrated, as usual (October 11, 1839), by a prism and lens; a water-prism, however, was used in the experiment, to command as large an area of spectrum as possible. The sun was poor and desultory; nevertheless in half an hour there was an evident commencement of whitening from the fiducial yellow ray to the mean red. In two hours and a half, the sunbeam continuing very much interrupted by clouds, the effect was marked by a considerable white patch extending from the extreme red to the end of the violet ray, but not traceable beyond that limit. Its commencement and termination were, however, very feeble, graduating off insensibly; but at the maximum, which occurred a little below the fiducial point (corresponding nearly with the orange rays of the luminous spectrum), the blue colour was completely discharged. Beyond the violet there was no indication of increase of colour, or of any other action. I do not find that this paper is discoloured by mere radiant heat unaccompanied with light."

Dr. George Wilson of Edinburgh made some exceedingly interesting experiments on the influence of sun light over the action of the dry gases on organic colours. The results arrived at were communicated to the British Association, and an abstract of the communication is published in their transactions. The experiments were on chlorine, sulphurous acid, sulphuretted hydrogen, carbonic acid, and a mixture of sulphurous and carbonic acid, oxygen, hydrogen and nitrogen on organic colouring matters. "I had ascertained," says Dr. George Wilson, "the action of the gases mentioned already on vegetable colouring matters, so arranged, that both colouring matter and gas should be as dry as possible, the aim of the inquiry being to elucidate the theory of bleaching, by accounting for the action of dry chlorine upon dry colours. In the course of this inquiry, I ascertained that in darkness dry chlorine may be kept for three years in contact with colours without bleaching them, although when moist it destroys their tints in a few seconds (see BLEACHING); and I thought it desirable to ascertain whether dry chlorine was equally powerless as a bleacher when assisted by sunlight. The general result of the inquiry was, that a few weeks sufficed for the bleaching of a body by chlorine in sunlight, where months, I may even say years, would not avail in darkness." The form of the experiment was as follows. Four tubes were connected together so as to form a continuous canal, through which a current of gas could be sent. Each tube contained a small glass rod on which seven pieces of differently coloured papers were spiked. It is not necessary here to state the colours employed, suffice it to say, that all the tubes thus contained seven different coloured papers, of different origins, and easily distinguishable by the eye. They were arranged in the same order in each tube, and were prepared as nearly as possible of the same shade. These papers were carefully deprived of every trace of moisture by a current of very dry air. The tubes were then filled with the gas, also dried, on which the experiment was to be made. One tube of each series was kept in darkness, two others were exposed in a western aspect behind glass, and the other was turned to the south in the open air.

The results were as follows:—In the dark chlorine tube the colours were very little altered, and would probably have been altered less had not the tube been frequently exposed to light for the sake of examination. In the western tube, the original grey and green wallflower papers became of a bright crimson, the blue litmus bright red, and the brown rhubarb yellow. The whole of the chlorine had apparently entered into combination with the colouring matters for the yellow tint of the gas had totally disappeared. In the southern tube the colour of the chlorine could still be seen, the reddening action was less decided, and the bleaching action was more powerfully evinced. The general result was that the action of sunlight is less uniform than might have been expected in increasing the bleaching power of chlorine, or while some tints rapidly disappeared under its action assisted by light, other colours remained, in apparently the very same circumstances, unaffected.

Sulphurous acid, if thoroughly dried, may be kept for months in contact with dry colours without altering them; under the influence of sunlight it however recovers to some extent its bleaching power.

Sulphuretted hydrogen acts as a weak acid, and readily as a bleacher when moist, and becomes inactive in both respects if made dry and kept in darkness. With the assistance of sunlight it recovers in no inconsiderable degree its bleaching power.

Oxygen is a well known bleaching agent, but when dry its action upon colouring matter in the dark is extremely slow. In sunlight, however, it recovers its bleaching power.

Carbonic acid, when dry in darkness, loses all power on colouring matter, but a faint bleaching action is exerted by it under exposure to sunlight.

Hydrogen is without any action when dry upon colours, but it acquires a slight decolorising power when exposed to sunshine.

"The general result," concludes Dr. George Wilson, "of this inquiry, so far as it has yet proceeded, is, that the bleaching gases, viz. chlorine, sulphurous acid, sulphuretted hydrogen, and oxygen, lose nearly all their bleaching power, if dry and in darkness, but all recover it, and chlorine in a most marked degree, by exposure to sunlight."

All these experiments appear to show that the action of the solar rays on vegetable colours is dependent upon the power possessed by one set of rays to aid in the oxidation or chemical changes of the organic compound constituting the colouring matter. The whole matter requires careful investigation.

It is a proved fact, that colouring matters, either from the mineral or the vegetable kingdoms, are much brighter when they are precipitated from their solutions in bright sunshine, than if precipitated on a cloudy day or in the dark. It must not be supposed that all the changes observed are due to chemical action; there can be no doubt but many are purely physical phenomena, that is, the result of molecular change, without any chemical disturbance.

LIGHT, ELECTRIC. See **ELECTRIC LIGHT.**

LIGHTHOUSE. The importance of lights of great power and of a distinguishable character around our coasts is admitted by all. One of the noblest efforts of humanity is certainly the construction of these guides to the mariners upon rocks which exist in the tracks of ships, or upon dangerous shores and the mouths of harbours. This is not the place to enter largely upon any special description of the lights which are adopted around our shores; a brief account only will be given of some of the more remarkable principles which have been introduced of late years by the Trinity Board.

The early lighthouses appear to have been illuminated by coal or wood fires contained in "chanfliers." The Isle of Man light was of this kind until 1816. The first decided improvement was made by Argand, in 1784, who invented a lamp with a circular wick, the flame being supplied by an external and internal current of air. To make these lamps more effective for lighthouse illumination, and to prevent the ray of light escaping on all sides, a reflector was added in 1780 by M. Lenoir; this threw the light forward in parallel rays towards such points of the horizon as would be useful to the mariner. Good reflectors increase the luminous effect of a lamp about 400 times; this is the "catoptric" system of lighting. When reflectors are used, there is a certain quantity of light lost, and the "dioptric" or *refracting* system, invented by the late M. Augustin Fresnel in 1822 is designed to obviate this effect to some extent: the "catadioptric" system is a still further improvement, and acts both by refraction and reflexion. Lights of the first order have an interior radius or focal distance of 36.25 inches, and are lighted by a lamp of four concentric wicks, consuming 370 gallons of oil per annum.

The appearance of light called short eclipses has hitherto been obtained by the following arrangement. —

An apparatus for a fixed light being provided, composed of a central cylinder and two zones of catadioptric rings forming a cupola and lower part, a certain number of lenses are arranged at equal distances from each other, placed upon an exterior movable frame making its revolution around the apparatus in a given period. These lenses, composed of vertical prisms, are of the same altitude as the cylinder, and the radius of their curves is in opposite directions to those of the cylinder, in such a manner that at their passage they converge into a parallel pencil of light, and the divergent rays emitted horizontally from the cylinder producing a brilliant effect, like that obtained by the use of annular lenses at the revolving lighthouses.

Before proceeding with the description of the lenses, the following notices may be of interest: —

The Eddystone Lighthouse $9\frac{1}{2}$ miles from the Rame Head, on the coast of Cornwall, was erected of timber by Winstanley in 1696-98, and was washed away in

1703. It was rebuilt by Rudyard in 1706, and destroyed by fire in 1735. The present edifice was erected by Smeaton 1757-59. Tallow candles were used in the first instance for the lights; but in 1807 argand lamps, with paraboloidal reflectors of silvered copper were substituted.

The Skerryvore Rocks, about 12 miles south-west of Tyree on the coast of Argyshire, lying in the track of the shipping of Liverpool and of the Clyde had long been regarded with dread by the mariners frequenting these seas. The extreme difficulty of the position, exposed to the unbroken force of the Atlantic Ocean, had alone deterred the commissioners of northern lights from the attempt to place a light upon this dangerous spot; but in 1834 they caused the reef to be surveyed, and in 1838 Mr. Alan Stevenson, their engineer, inheriting his father's energy and scientific skill, commenced his operations upon a site from which "nothing could be seen for miles around but white foaming breakers, and nothing could be heard but the howling of the winds and the lashing of the waves." His design was an adaptation of Smeaton's tower of the Eddystone to the peculiar situation, a circumstance with which he had to contend. He established a circular base 42 feet in diameter, rising in a solid mass of gneiss or granite, but diminishing in diameter to the height of 26 feet, and presenting an even concave surface all around to the action of the waves. Immediately above this level the walls are 9.58 feet thick, diminishing in thickness as the tower rises to its highest elevation, where the walls are reduced to 2 feet in thickness, and the diameter to 16 feet. The tower is built of granite from the islands of Tyree and Mull, and its height from the base is 138 feet 8 inches. In the intervals left by the thickness of the walls are the stairs, a space for the necessary supply of stores, and a not uncomfortable habitation for three attendants. The rest of the establishment, stores, &c., are kept at the depot in the island of Tyree. The light of the Skerryvore is revolving, and is produced by the revolution of eight annular lenses around a central lamp, and belongs to the first order of dioptric lights in the system of Fresnel, and may be seen from a vessel's deck at a distance of 18 miles. — *Lord De Mûlroy, Juror's Report, Great Exhibition, 1851.*

Some of the lenticular arrangements must now claim attention. Large lenses, or any large masses of glass, are liable to strain, which by dispersing, occasion a loss of much light.

"In order to improve a solid lens formed of one piece of glass whose section is $A, m, p, n, F, z, D, C, A$, Hutton proposed to cut out all the glass left white in the figure (1132), namely, the portions between $m p$ and $n o$, and between $n o$ and the left hand surface of $D E$. A lens thus constructed would be incomparably superior to a solid one, but such a process we conceive to be impracticable on a large scale, from the extreme difficulty of polishing the surfaces $A m, n p, o n, r a$, and the left hand surface of $D E$; and even if it were practical, the greatest imperfections of the glass might happen to occur in the parts which are left. In order to remove these imperfections and to construct lenses of any size," says Sir David Brewster,

"I proposed in 1811 to build them up of separate zones or rings, each of which rings was again to be composed of separate segments, as shown in the front view of the lens in fig. 1133. This lens is composed of one central lens $A n c u$, corresponding with its section $D E$ in fig. 1132; of a middle ring $G K L T$, corresponding to $C D E F$, and consisting of 4 segments; and another ring $X P a T$, corresponding to $A C F n$, and consisting of 8 segments. The preceding construction obviously puts it in our power to execute those lenses to which I have given the name of *polyzonal lenses*, of pure flint glass free from veins; but it possesses another great advantage, namely, that of enabling us to correct very nearly the spherical aberration by making the foci of each zone coincide." — *Brewster.*

This description will enable the reader to understand the system which has been adopted by Fresnel and carried out by the French government, and by our own commissioners of lights.

In the fixed dioptric light of Fresnel, the flame is placed in the centre of the apparatus, and within a cylindric reflector of glass, of a vertical refracting power, the breadth and height of a strip of light emitted by it being dependent upon the size of the flame and the height of the reflector itself; above and below is placed a series of reflecting prismatic rings or zones for collecting the upper and lower divergent rays, which, falling upon the inner side of the zone are refracted, pass through the second side where they suffer total reflection, and passing out on the outer side of the zone, are again refracted. The effect of these zones is to lengthen the vertical strip of

light, the size of which is dependent upon the breadth of the flame, and the height of the apparatus.

In Fresnel's revolving lighthouse, a large flame is placed in the centre of a revolving frame which carries a number of lenses on a large scale and of various curvatures for the avoidance of spherical aberration. With the view of collecting the divergent rays above the flame, an arrangement of lenses and silvered mirrors is placed immediately over it. By this compound arrangement the simply revolving character of the apparatus is destroyed, as, in addition to the revolving flash, a vertical and fixed light is at all times seen, added to which a great loss of light must be sustained by the loss of metallic reflectors. In 1831, Messrs. Wilkins and Levernian, exhibited a catadioptric apparatus of great utility. It was thus described by the exhibitors:—

The first improvement has special reference to the light, and produces a considerable increase in its power, whilst the simplicity of the optical arrangements is also repaired. It consists, firstly, in completely dispensing with the movable central cylindrical lenses; secondly, it replaces these by a single revolving cylinder composed of four annular lenses and four lenses of a fixed light introduced between them; but the number of each varying according to the succession of flashes to be produced in the period of revolution.

The second improvement, of which already some applications that have been made serve to show the importance, consists in a new method of arranging the revolving parts, experience having shown that the arrangements at present in use are very faulty. A short time is sufficient for the action of the friction rollers, revolving on two parallel planes, to produce by a succession of cuttings a sufficiently deep groove to destroy the regularity of the rotatory movement. To obviate this great inconvenience the friction rollers are so placed and fitted, on an iron axis with regulating screws and traversing between two bevelled surfaces, that when an indentation is made in one place they can be adjusted to another part of the plates which is not so worn.

The third improvement produces the result of an increase of the power of the flashes in revolving lighthouse apparatus in double what has been obtained hitherto. By means of lenses of vertical prisms placed in the prolongation of the central annular lenses, the divergent rays emerging from the catadioptric zone are brought into a straight line, and a coincidence of the three lenses is obtained.

The whole of the prisms, lenses, and soles are mounted with strength and simplicity, accurately ground and polished to the correct curves according to their respective positions, so as to properly develop this beautiful system of Fresnel. The glass of which they are composed should be of the clearest crystal colour, and free from that green hue which so materially reduces the power of the light, and is considered objectionable for apparatus of this kind. The lamp by which the apparatus is to be lighted consists of a concentric burner with four circular wicks attached to a lamp of simple construction, the oil being forced up to the burner by atmospheric pressure only, so that there are no delicate pumps or machinery to become deranged.

Stevenson's revolving lighthouse.—This apparatus consists of two parts. The principal part is a right octagonal hollow prism composed of eight large lenses, which throw out a powerful beam of light whenever the axis of a single lens comes in the line between the observer and the focus. This occurs once in a minute, as the frame which bears the lens revolves in eight minutes on the rollers placed beneath. The subsidiary parts consist of eight pyramidal lenses inclined at an angle of 30° to the horizon, and forming together a hollow truncated cone, which rests above the flame like a cap. Above these smaller lenses (which can only be seen by looking from below) are placed eight plane mirrors, whose surfaces being inclined to the horizon at 50° in the direction opposite to that of the pyramidal lenses, finally cause all the light made parallel by the refraction of these lenses to leave the mirror in a horizontal direction. The only object of this part is to turn to useful account, by prolonging the duration of the flash, that part of the light which would otherwise escape into the atmosphere above the main lenses. This is effected by giving to the upper lenses a slight horizontal divergence from the vertical plane of the principal lenses. Below are five tiers of totally reflecting prisms, which intercept the light that passes below the great lenses, and by means of two reflections and an intermediate refraction project them in the shape of a flat ring to the horizon.

Stevenson's fixed dioptric apparatus of the first order (same as that at the Isle of May, with various improvements). The principal part consists of a cylindric belt of glass which surrounds the flame in the centre, and by its action refracts the light in a vertical direction upward and downward, so as to be parallel with the focal plane of the system. In this way it throws out a flat ring of light equally intense in every direction. To near observers, this action presents a narrow vertical band of light,

depending for its breadth on the extent of the horizontal angle embraced by the eye. This arrangement therefore fulfils all the conditions of a fixed light, and surpasses in effect any arrangement of parabolic reflectors. In order to save the light which would be lost in passing above and below the cylindrical belt, curved mirrors with their common focus in the lamp were formerly used; but by the present engineer, the adaptation of *catadioptric zones* to this part of the apparatus was, after much labour, successfully carried out. These zones are triangular, and act by *total reflexion*, the inner face *refracting*, the second *totally reflecting*, and the third or outer face, a second time *refracting*, so as to cause the light to emerge *horizontally*. The apparatus has received many smaller changes by the introduction of a new mode of grouping the various parts of the frame work, by which the passage of the light is less obscured in every azimuth.

Mechanical lamps of four wicks, are used in these lighthouses; in these the oil is kept continually overflowing by means of pumps which raise it from the cistern below; thus the rapid carbonisation of the wicks, which would be caused by the great heat, is avoided. The flames of the lamp reach their best effect in three hours after lighting, i. e. after the whole of the oil in the cistern, by passing and re-passing over the wicks repeatedly, has reached its maximum temperature. After this the lamp often burns 14 hours without sensible diminution of the light, and then rapidly falls. The height varies from 16 to 20 times that of the argand flame of an inch in diameter; and the quantity of oil consumed by it is greater nearly in the same proportion.

In *Sternum's* ordinary *parabolic reflector*, rendered *holophotal* (where the entire light is parallelised) by a portion of a *catadioptric annular lens*, the back part of the parabolic conoid is cut off, and a portion of a spherical mirror substituted, so as to send the rays again through the flame; while his *holophotal catadioptric annular lens apparatus* is a combination of a hemispherical mirror and a lens having *totally-reflecting zones*; the peculiarity of this arrangement is, that the *catadioptric zones*, instead of transmitting the light in parallel horizontal plates, as in *Fresnel's* apparatus, produce, as it were, an extension of the lenticular or quaquaversal action of the central lens by assembling the light around its axis in the form of concentric hollow cylinders.

Mr. Chance, of Birmingham, constructed a lighthouse which may be regarded as *Fresnel's* revolving light rendered *holophotal*. This arrangement was divided into three compartments, the upper and lower of which were composed respectively of thirteen and six *catadioptric zones* which produce the vertical strip of light extending the whole length of the apparatus, and is similar to *Fresnel's* dioptric light. The central or *catoptric* compartment consisted of eight lenses of three feet focal length, each of which was the centre of a series of eleven concentric prismatic rings, designed to produce the same refractive effect as a solid lens of equal size. These compound lenses were mounted upon a revolving frame and transmitted horizontal flashes of light as they successively rotated. The motion was communicated to the frame by a clock movement, and performs one revolution in four minutes; consequently, as there are eight lenses, a flash of light is transmitted every thirty seconds to the horizon.

LIGNEOUS MATTER is vegetable fibre. See FINE VEGETABLE.

LIGNITE Under BROWN COAL, BROWN COAL, and COAL, the characteristics of lignite have already received attention, therefore little farther need be said. The term lignite should be confined to fossil wood, or, still more correctly to wood which has undergone one of the changes leading towards the production of coal. If wood is buried in moist earth there is the production of carbonic acid from the elements of the wood, and the wood is changed into either lignite or brown coal. Lignite and coal differ chemically from each other. Lignite yields by dry distillation acetic acid and acetate of ammonia, whereas coal produces only an ammoniacal liquor. (*Kiemers*) Woody fibre gives rise to acetic acid; therefore, lignite must still contain undecomposed woody fibre. The following table gives the composition of several well known lignites.

	Carbon	Hydrogen	Oxygen and Nitrogen	Earthy	Consist.
From Pittsburg - -	77.9	2.6	19.5	1	Karsten
" Hungary - -	67.3	4.3	-	0.3	Newborth
" the Rhine - -	73.4	4.2	20.1	1.8	Rognault
" Meisner - -	65.6	5.2	19.0	2.3	Gtäger
" Bovey Heathfield -	67.9	5.8	21.8	-	Vaux

In Prussia, Austria, and many other parts of the continent, lignite forms a very

important product, being largely employed for domestic and for manufacturing purposes. In this country, with the single exception of the Bovey Heathfield formation, which is used in the adjoining pottery, lignite is not employed.

LIGNUM-VITÆ, or *Guaiacum* (*Guaiacum officinale* and *G. sanctum*), a very hard and heavy wood. The fibrous structure of this wood is very remarkable; the fibres cross each other sometimes as obliquely as at an angle of 30 degrees with the axis, as if one group of the annual layers wound to the right the next to the left and so on, with any exactitude. The wood can hardly be split, it is therefore divided by the saw. *Lignum-vitæ* is much used in machinery for rollers, presses, mills, &c., and for pestles and mortars, sheers for ship's blocks, skittle balls, and a great variety of other works requiring hardness and strength.

The gum guaiacum of the apothecary is extracted from this wood.

ILLAC DYE. See CALICO-PRINTING, DYEING, AND ANILINE.

LIME. *Quicklime*, an *Oxide of Calcium*. This useful substance is prepared by expelling the native carbonate of lime to heat, by which the carbonic acid is expelled.

This operation is performed in a manner more or less perfect, by burning calcareous stones in kilns or furnaces.

Limestone used to be calcined in a very rude kiln, formed by inclosing a circular space of 10 or 15 feet diameter, by rude stone walls 4 or 5 feet high, and filling the cylindrical cavity with alternate layers of turf or coal and limestone broken into moderate pieces. A bed of brushwood was usually placed at the bottom, to facilitate the kindling of the kiln. Whenever the combustion was fairly commenced, the top, piled into a conical form, was covered in with soot, to render the calcination slow and regular. This method being found relatively inconvenient and ineffectual, was succeeded by a permanent kiln built of stones or brickwork, in the shape of a truncated cone with the narrow end undermost, and closed at bottom by an iron grate. Into this kiln, the fuel and limestone were introduced at the top in alternate layers, beginning of course with the former; and the charge was either allowed to burn out, when the layer was altogether removed at a door near the bottom, or the kiln was successively fed with fresh materials, in alternate beds, as the former supply sunk down by the calcination, while the thoroughly burnt lime at the bottom was successively raked out by a side door immediately above the grate. The interior of the lime kiln has been changed of late years from the conical to the elliptical form, and probably the best is that of an egg placed with its narrow end undermost, and truncated both above and below; the ground plot or bottom of the kiln being compressed so as to give an elliptical section, with a eye or draft-hole towards each end of that ellipse. A kiln thus arched in above gives a reverberatory heat to the upper materials, and also favours their falling freely down in proportion as the finished lime is raked out below; advantages which the conical form does not afford. The size of the draft-holes for extracting the quicklime, should be proportionate to the size of the kiln, in order to admit a sufficient current of air to ascend with the smoke and flame, which is found to facilitate the extrication of the carbonic acid. The kilns are called *perpetual*, because the operation is carried on continuously as long as the building lasts; and *draw-kilns*, from the mode of discharging them by raking out the lime into carts placed against the draft-holes. Three bushels of calcined limestone, or lime-shells, are produced on an average for every bushel of coals consumed. Such kilns should be built up against the face of a cliff, so that easy access may be gained to the mouth for charging, by making a sloping cart road to the top of the bank.

Figs 1134, 1135, 1136, 1137 represent the *lime-kiln* of Rudersdorf near Berlin, upon the continuous plan, excellently constructed for economising fuel. It is triple, and yields a threefold product. Fig 1136 is a view of it as seen from above; fig 1137, the elevation and general appearance of one side; fig 1134, a vertical section, and fig 1135, the ground plan in the line A n c n of fig 1134. The inner shaft fig 1135, has the form of two truncated cones, with their larger circular ends applied to each other; it has the greatest width at the level of the fire-door *b*, where it is 8 feet in diameter; it is narrower below, at the discharge door, and at the top orifice, where *R* is about 6 feet in diameter. The interior wall *d*, of the upper shaft is built with hewn stones to the height of 38 feet, and below that for 25 feet, with fire-bricks *d'* laid stepwise. This inner wall is surrounded with a mantle *e*, of limestone, but between the two there is a small vacant space of a few inches filled with ashes, in order to allow of the expansion of the interior with heat taking place without shattering the mass of the building.

The fire-grate, *h*, consists of fire-tiles, which at the middle, where the single pieces press together, lie upon an arched support *f*. The fire-door is also arched, and is secured by fire-tiles. *g* is the iron door in front of that orifice. The tiles which form the grate have 3 or 4 slots of an inch wide for admitting the air, which enters through the canal *k*.

The under part of the shaft from the fire to the hearth is 7 feet, and the outer enclosing wall is constructed of limestone, the lining being of fire-bricks. Here are the ash-

1134

1136

1125

1157

pit *i*, the discharge outlet *a*, and the canal *k*, in front of the outlet. Each ash pit is shut with an iron door, which is opened only when the space *i* becomes filled with ashes. These indeed are allowed to remain till they get cool enough to be removed without inconvenience.

The discharge outlets are also furnished with iron doors, which are opened only for taking out the lime, and are carefully luted with loam during the burning. The outside walls *lm* of the kiln, are not essentially necessary, but convenient, because they afford room for the lime to lie in the lower floor, and the fuel in the second. The several stories are formed of groined arches *n*, and platforms *p*, covered over with limestone slabs. In the third and fourth stories the workmen lodge at night. See fig 1137. Some enter their apartments by the upper door *q*; others by the lower door *a*. *r* is one of the chimneys for the several fireplaces of the workmen. *z*, *u*, *v* are stairs.

As the limestone is introduced at top, the mouth of the kiln is surrounded with a strong iron balustrade to prevent the danger of the people tumbling in. The platform is laid with rails *w*, for the waggons of limestone, drawn by horses, to run upon. *x* is another railway, leading to another kiln. Such kilns are named after the number of their fire-doors, single, twofold, threefold, fourfold, &c.; from three to five being the most usual. The outer form of the kiln also is determined by the number of the furnaces; being a truncated pyramid of equal sides, and in the middle of each alternate side, there is a fireplace, and a discharge outlet. A cubic foot of limestone requires for burning, ten and five-twelfths of a cubic foot of wood, and one and a half of turf.

When the kiln is to be set in action, it is filled with rough limestones, to the height of α , or to the level of the firing β ; a wood fire is kindled in α , and kept up till the lime is calcined. Upon this mass of quicklime, a fresh quantity of limestones is introduced, not thrown in at the mouth, but let down in buckets, till the kiln is quite full; while over the top a cone of limestones is piled up, about 4 feet high. A turf-fire is now kindled in the furnaces δ . Whenever the upper stones are well calcined, the lime

under the fire-level is taken out, the superior column falls in, a new cone is piled up, and the process goes on thus without interruption, and without the necessity of once putting a fire into it; for in the space *c n*, the lime must be always well calcined. The discharge of lime takes place every 12 hours, and it amounts at each time in a three-fold kiln, to from 20 to 24 Prussian *tonnen* of 6 imperial bushels each; or to 130 bushels imperial upon the average. It is found by experience that fresh-broken limestone, which contains a little moisture, calcines more readily than what has been tried by exposure for some time to the air; in consequence of the vapour of water promoting the escape of the carbonic acid gas; a fact well exemplified in distilling essential oils, as oil of turpentine and naphtha, which come over with the steam of water at upwards of 100° Fahr. below their natural term of ebullition. Six bushels of Rüdersdorf quicklime weigh from 250 to 300 pounds.

Anhydrous lime, or, as it is commonly called "*quicklime*," is an amorphous solid, varying much in coherence, according to the kind of rock from which it is obtained; its specific gravity varies from 2.3 to 3. Lime is one of the most infusible bodies which we possess; it resists the highest heats of our furnaces.

When exposed to air, quicklime rapidly absorbs water and crumbles into a powder, commonly known as *slaked lime*, which is a *hydrate of lime*.

Hydrate of lime when exposed to the air absorbs carbonic acid, and after long exposure it is converted into a mixture of carbonate of lime and hydrate of lime in single equivalents. Hydrate of lime is but slightly soluble in water, 729 to 733 parts of that fluid dissolving only 1 part of the lime at ordinary temperatures.

Hydrate of lime is applied to numerous purposes in the arts and manufactures. It is chiefly employed in the preparation of mortar for building purposes. See MORTAR.

The pure limes, prepared from the carbonates of lime, form an imperfect mortar suitable only for dry situations. In damp buildings or in wet situations they never set (as the process of hardening is technically termed), but always remain in a pulpy state. General Pasley says, "The unsuitableness of pure lime for the purposes of hydraulic architecture has been proved by several striking circumstances that have come under my personal observation, of which I shall only mention a few. First, a great portion of the boundary wall of Rochester Castle having been completely undermined, nearly throughout its whole thickness, which was considerable, whilst the upper part of the same wall was left standing, I had always ascribed this remarkable breach to violence, considering it as having been the act of gunners intending to destroy the wall for the sake of the stone; but on examining it more accurately after I had begun to study the subject of limes and cements, I observed that the whole of the breached part was washed by the Medway at high water, and that all the mortar of a small portion of the back part of the foot of the wall still left standing was quite soft, but that towards the ordinary high water level it became a little harder, and above that level it was perfectly sound. I observed the same process at the outer wall of Cockham Wood Fort, on the left bank of the Medway below Chatham, of which the upper part was standing, whilst the lower part of it had been gradually ruined by the action of the river at high water destroying the mortar."

Observations on limes, calcareous cements, &c. — The peculiar conditions necessary to insure a good and useful mortar for building purposes, and, the peculiarities of the hydraulic mortars or cements, will be treated of under MORTAR, which see.

LIMESTONE. (*Calcaire*, Fr; *Kalkstein*, Germ.) A great variety of rocks contain a sufficient quantity of lime in combination to be called limestones.

Chalk is an earthy massive opaque variety, usually soft and without lustre, and may be regarded as a tolerably pure carbonate of lime. Carbonate of lime dissolves in 1000 parts of water charged with carbonic acid. (*Shalk f.*) Fresenius states that it dissolves in 8334 parts of boiling water and in 10,601 parts of water at ordinary temperatures.

Carbonate of lime is found in nature more or less pure, both crystallised perfectly, as in calc spar and aragonite imperfectly; as in granular limestone; and in compact masses, as in common limestone, chalk, &c.

Stalactitic carbonate of lime, frequently called concretionary limestone, is formed by the infiltration of water through rocks containing lime, which is dissolved out, and as it slowly percolates the rocks into cavernous openings, the water parts with its carbonate of lime, which is deposited in zones more or less undulated, which have a fibrous structure from the crystalline character of the concretionary lime. The long fibrous pieces called stalactites show these fibres very beautifully. The straliform masses called stalagmites exhibit a similar structure, varied only by the conditions under which they are formed. A very remarkable stalagmitic limestone found in Egypt is known as oriental alabaster.

True *Alabaster* is a sulphate of lime (see ALABASTER), but the stalagmitic carbonate is not unfrequently called by this name.

Increasing concretionary limestones differ but little from the above. They are depos-

from calcareous springs which are common in some parts of Derbyshire, Yorkshire, and other places. It is a common practice to place vegetable substances in those springs; they then become incrustated with carbonate of lime, and are sold as petrifications, which they are not. In volcanic districts many very remarkable springs of this character exist. One of the most remarkable is at the baths of San Filippo in Tuscany, where the water flows in almost a boiling state; carbonate of lime here appears to be held in solution by sulphuretted hydrogen, which flies off when the water issues to day. Dr. Vegny has taken advantage of this property of the spring to obtain basso-relievo figures of great whiteness and solidity by occasioning the lime to deposit in sulphur moulds.

Agaric mineral, Spongy limestone, Rock milk, is found at the bottom of and about lakes whose waters are impregnated with lime. The calcareous tufa of Derbyshire is of this character; it may be studied in every stage of formation.

Travertine, which served to construct most of the monuments in ancient Rome, appears to have been formed by the deposits of the Anio and the Solfatara of Tivoli. The temples of Paestum, which are of extreme antiquity, have been built with a *travertine*, formed by the waters which still flow in this territory.

Compact limestone has a compact texture, usually an even surface of fracture, and dull shades of colour.

Granular limestone includes common statuary and architectural marble, and has a texture something like loaf-sugar. (See MARBLE.) Under those two heads are grouped a great number of varieties.

Oolite or rice stone consists of spherical grains of various sizes, from a millet seed to a pea or even an egg.

Coarse grained limestone. Coarse lias has been referred to this head.

Marly limestone. Lake and fresh-water limestone formation, texture fine grained, more or less dense; apt to crumble down in the air; colour white or pale yellow; fracture rough grained, somewhat conchoidal; somewhat tenacious. Texture occasionally cavernous, with cylindrical winding cavities. This true limestone must not be confounded with lime marl, which is composed of calcareous matter and clay.

Siliceous limestone. A combination of silica and carbonate of lime, varying very much in the proportions and sometimes passing from *cherty limestone* into *chert*. It scratches steel, and leaves a siliceous residuum after the action of muriatic acid.

Stinkstone or Swinestone. A carbonate of lime combined with sulphur and organic matter. It emits the smell of sulphuretted hydrogen by a blow or by friction. It occurs at Assynt, in Sutherlandshire, in Derbyshire, and some parts of Ireland.

Bituminous limestone. Limestone containing various hydrocarbon compounds, diffusing by the action of fire a bituminous odour, and becoming white when burnt.

Limestones of whatever kind may be referred to deposition effected by chemical change. The immense lapse of time required to form the great limestone ranges of this country can scarcely be estimated. Professor Phillips has the following remarks on this:—

"It is certain that while the sandstones, shales, coals, and thin oolitic limestones of the North York moors were deposited upon the lias, a deposit almost wholly calcareous was occasioned near Bath. The whole time consumed was the same in each locality. We may, therefore, perhaps infer the comparative rate of deposition of the oolite and the sandstones. The total thickness of the mass in Yorkshire is about 750 feet, of which about 20 may be called limestone; of that near Bath 480, of which nearly half is sand and clay with calcareous matter interspersed. Hence we have the proportion of three feet of sandstone deposited in the same time as one of limestone. Another instance is afforded, by comparing the sections of the lower carboniferous limestone in Derbyshire and in Tyndale. In the former tract we may take 750 feet as the thickness of limestone, with no admixture of sands or clays; in the latter; the contemporaneous strata are at least 1,750 feet thick, and contain 367 feet of limestone, and 1,283 feet of sands and clays, &c. consequently, 3.3 of limestone correspond in time to 1,283 of sand, clays, and coal, or 1 to 3.3."

The formation of limestone under different circumstances is an interesting study. Some of our great limestone formations indicate a marine, while others very clearly show a fresh water origin. Mr. Jukes, in his *Student's Manual of Geology*, says: "The marine depositions of carbonate of lime now taking place are best studied in coral reefs. In almost all tropical seas increasing patches or small banks of living coral are to be found along the shores, wherever they consist of hard rock and the water is quite clear. In the Indian and Pacific Oceans, however, far away from any land, huge masses of coral rock rise up from vast and unknown depths just to the level of low water. These masses are often unbroken for many miles in length and breadth, and groups of such masses, separated by small intervals, occur over spaces sometimes 400 or 500 miles long by 50 or 60 in width. The barrier reef along the

north-east coast of Australia is composed of a chain of such masses, and is more than 1000 miles long, from 10 to 90 miles in width, and rises at its seaward edge to depths which in some places certainly exceed 1800 feet. These reef masses consist of living corals only at their upper and outer surface, all the interior is composed of dead corals and shells, either whole or in fragments, and the calcareous portions of other marine animals. The interstices of the mass are filled up and compacted together by calcareous sand and mud, derived from the waste and debris, the great and tear of the corals and shells, and by countless myriads of minute organisms, mostly calcareous also. The surface of a reef when exposed at low water is composed of solid looking stone, which is often capable of being split up and lifted in slabs, bearing no small resemblance to some of our oldest limestones. . . . Guided by these facts and observations we may form tolerably accurate notions of the mode of origin of all our marine limestones, and attribute to them an organic-chemical origin, taking into account, at the same time, how easily they may have been subsequently altered in texture by the metamorphic action either of water or heat." Dr. Lyon Playfair suggests two additional modes by which a chemical precipitation of carbonate of lime might in some places be formed on the bottom of the sea. He says most rivers contain small quantities of silicate of potash; and when this is carried into the sea, some of the carbonic acid contained therein may unite with the potash, thus rendering possible a precipitation of carbonate of lime in a solid form, and also of silica. Marine vegetables also, like terrestrial vegetation, require carbonic acid, and, by extracting it from sea water, may reduce the amount in particular localities below that which is necessary to keep all the carbonate of lime in a fluid state, and thus render a solid precipitation of that substance possible. — *De la Roche*.

"Limestones," says Mr. Jukes, "may be hard or soft, compact, concretionary, or crystalline, consisting of pure carbonate of lime or containing silica, alumina, iron, &c., either as mechanical admixtures or as chemical deposits along with it. Different varieties of limestone occur in different localities, both geographical and geological, peculiar forms of it being often confined to particular geological formations over wide areas, so that it is much more frequently possible to say what geological formation a specimen was derived from, by the examination of its lithological characters, in the case of limestone than in that of any other rock. Compact limestone is a hard smooth fine-grained rock, generally bluish-grey, but sometimes yellow, black, red, white or mottled. It has either a dull earthy fracture or a sharp splintery and conchoidal one. It will frequently take a polish, and when the colour is a pleasing one is used as an ornamental marble. Crystalline limestone may be either coarse or fine-grained, varying from a rough granular rock of various colours to a pure white fine-grained one, resembling loaf-sugar in texture. This latter variety is sometimes called *saccharine*, sometimes *statuary marble*."

Oolitic limestone includes Bath stone, Portland stone, and Caen stone.

Pisolite is a variety of oolite, in which the concretions become as large as peas.

Nummulitic limestone, *Cymensis*, *Crinoidal* limestones are so called from the fossils which the rock contains.

Shell limestone or *muschelkalk* has its name in the same way from its composition.

Cipolino is a granular limestone containing mica.

Majolica, a white and compact limestone.

Scaglia, a red limestone in the Alps. For the three last see MARBLE.

LIMESTONE, **MAGNESIAN**, see **DOLOMITE**. (*Dolomie*, Fr.; *Bitterkalk*, *Talkspath*, Germ.), is a mineral which crystallises in the rhombohedral system. Spec. grav. 2.85; scratches calc-spar; does not fall spontaneously into powder when calcined, as common limestone does. It consists of 1 prime equivalent of carbonate of lime = 50, associated with 1 of carbonate of magnesia = 42.

Massive magnesian limestone, is yellowish-brown, cream-yellow, and yellowish-grey; brittle. It dissolves slowly and with feeble effervescence in dilute muriatic acid; whence it is called *Calcaire lent dolomieu*, by the French mineralogists. Specific gravity 2.6 to 2.7.

Near Sunderland, it is found in flexible slabs. The principal range of hills composing this geological formation in England, extends from Sunderland to the north-east coast to Nottingham, and its beds are described as being about 300 feet thick on the east of the coal field in Derbyshire, which is near its northern extremity. — H.W. B.

LIME TREE (*Tilia Europæa*). The well-known linden tree, common to all Europe. The wood is very light-coloured, fine and close in the grain, and when properly seasoned, not liable to warp. It is much used in the manufacture of piano fortes and harps. It is made into cutting boards for carriers, shoemakers, &c., as it does not turn the knife in any direction of the grain, nor injure the edge.

Lime tree wood is especially useful for carving, from its even texture and freedom

from knots. The beautiful works of Gibbons at Hampton Court, at Windsor, and at Chatsworth, are executed in lime tree wood.

The no less beautiful works of our celebrated living wood carver, Rogers, are executed in this wood.

LIMOGE WARE. See **POTTERY.**

LIMONITE. A name for several varieties of iron ore, such as the brown hematite and bog iron ore. There is much difficulty in distinguishing the various kinds of iron ore, they shade so gradually one into the other; but it is clearly a very unscientific mode of proceeding to group things unlike each other under a common name.

LINSEYS, sometimes called *linsey-woolsey*; being a combination of flax and wool, which are woven into coarse cloth, usually employed to clothe those who are entirely dependent on public charity.

LINEN. See **FLAX**, and **TEXTILE FABRICS.**

LINEN distinguished from cotton. Cotton may be distinguished from linen or flax by immersing the former, well washed and dried, for about a minute in strong sulphuric acid. It is then to be withdrawn and washed with water containing a little alkali. The cotton will dissolve as a gummy mass, while the linen will retain its thready texture.

The manufacture of linens is carried on extensively in the north of Ireland, and on the continent in Bohemia, Moravia, Silesia, and Galicia. Of the entire production, independent of the Irish linen, about five-twelfths are brought into the market, and of this quantity the bulk must be of domestic manufacture, since few great linen manufactures exist in Austria. Within the Austrian dominions, among the linen fabrics, table-cloths and napkins, veils, cambrics, dimities, twills, and drills are important articles. In the next rank we must place the manufacture of thread, especially in Bohemia, Moravia, and Lombardy. The tape manufacture is of less consequence; and as to the business of dyeing and printing, that has been almost entirely absorbed by the cotton manufacture, and is now in requisition for thread and handkerchiefs only.

As the loss resulting from the processes of weaving, bleaching, &c. is estimated at about 10 per cent. the net aggregate of these manufactures of linen, thread, &c., may be assumed at, say, 1,037,000 cwt.; of which quantity about 450,000 cwt. come into the market, the rest being absorbed by domestic consumption. Since, upon an average of the five years from 1843 to 1847, there appear to have been imported from abroad only 242 cwt. whereas the average of exports for the same period shows 42,609 cwt., it follows that there remained for home consumption about 1,000,000 cwt. Thus, on a population of 38,000,000 of persons, about 2½ lbs. would fall to the share of each; but this estimate falls much below the truth, when we consider that the national costume in Hungary and Galicia requires more than double the quantity we have allowed for. In fact the crop of flax is estimated to be 10 per cent. higher than is given in the official reports; but the consumption of even 3 lbs. per head, which would thus result, is yet smaller than in reality it must be. In the imperial army of Austria the quantity used up annually by each man averages more than 7 lbs.

In the above statistics of the manufacture of linen goods no allowance has been made for the extensive production of rope work and the like.

From the article **FLAX**, reference has been made to this article for available information in the statistics of the production of the raw material and of the finished article in this country. The following simple tables will fully set forth the value of this important manufacture.

After the information already conveyed to the reader in the article **FLAX**, what has been said with regard to **COTTON MANUFACTURE**, and the additional matter in the article **TEXTILE FABRICS**, it does not appear necessary to say anything more on the subject of linen manufacture.

Imports of Flax in 1857.

LINSEED. (*Grains de lin*, Fr.; *Leinsame*, Germ.) The seed of the flax, *Linum Catharticum*, which is indigenous to our islands, and is cultivated extensively in this and other countries for its seed, and for flax. Linseed contains in its dry state, 11.265 of oil; 0.146 of wax; 2.4908 of a soft resin; 0.350 of a colouring resinous matter; 0.926 of a yellowish substance analogous to tannin; 0.134 of gum; 15.12 of vegetable mucilage; 1.45 of starch; 2.932 of gluten; 2.782 of albumine; 10.881 of saccharine extractive; 44.392 of envelopes, including some vegetable mucilage. It contains also free acetic acid; some acetate, sulphate, and muriate of potash, phosphate and sulphate of lime; phosphate of magnesia; and silica.

LINSEED OIL is obtained from linseed by first bruising the seeds, grinding them, and subjecting them to violent pressure, either by means of wedges, or of the hydraulic or screw press. Cold drawn linseed oil is obtained cold, and is paler coloured, less odorous, and has less taste than that which is obtained when heat is applied.

It is usual to employ a steam heat of about 200° Fahr. By cold expression the seeds yield about 20 per cent., while by the aid of heat nearly 27 per cent. of oil can be obtained. The ultimate composition of linseed oil is carbon 76.014, hydrogen 11.351, and oxygen 12.635; its proximate constituents being oleic and margaric acids, and glycerine. Linseed oil is much used as a vehicle for colours by the painter. If linseed oil is exposed in a thin coat to the air it absorbs oxygen and becomes tenacious, and in many respects like caoutchouc: upon this property mainly depends its use in the arts. To secure this more readily a drying process is adopted, which must be described.

When linseed oil is carefully agitated with acetate of lead (tribasic acetate of lead), and the mixture allowed to clear by settling, a copious white cloudy precipitate forms, containing oxide of lead, whilst the raw oil is converted into a drying oil of a pale straw colour, forming an excellent varnish, which, when applied in thin layers, dries perfectly in twenty four hours. It contains from four to five per cent. of oxide of lead in solution. The following proportions appear to be the most advantageous for its preparation.

In a bottle containing 4½ pints of rain water, 15 ounces of neutral acetate of lead are placed, and when the solution is complete, 15 ounces of litharge in a very fine powder are added; the whole is then allowed to stand in a moderately warm place, frequently agitating it to assist the solution of the litharge. This solution may be considered as complete when no more small scales are apparent. The deposit of a shining white colour (cerbasic acetate of lead) may be separated by filtration. This conversion of the neutral acetate of lead into vinegar of lead, by means of litharge and water, is effected in about a quarter of an hour, if the mixture be heated to ebullition. When heat is not applied, the process will usually take three or four days. The solution of vinegar of lead, or tribasic acetate of lead, thus formed, is sufficient for the preparation of 22 lbs. of drying oil. For this purpose, the solution is diluted with an equal volume of rain water, and to it is gradually added, with constant agitation, 22 lbs. of oil, with which 16 ounces of litharge have previously been mixed.

When the points of contact between the lead solution and the oil have been frequently renewed by agitation of the mixture three or four times a day, and the mixture allowed to settle in a warm place, the limpid straw-coloured oil rises to the surface, leaving a copious whitish deposit. The watery solution rendered clear by filtration, contains intact all the acetate of lead first employed, and may be used in the next operation, after the addition to it as before of 16 ounces of litharge.

By filtration through paper or cotton the oil may be obtained as limpid as water, and by exposure to the light of the sun it may also be bleached.

Should a drying oil be required absolutely free from lead, it may be obtained by the addition of dilute sulphuric acid to the above, when, on being allowed to stand, a deposit of sulphate of lead will take place, and the clear oil may be obtained free from all trace of lead.

Linseed oil was at one time much used in the preparation of a liniment, which, as it is one of the very best possible applications to a burnt surface, cannot be too generally known. If equal parts of lime-water and linseed oil are agitated together, they form a thick liniment, which may be applied to the burn with a brush or feather. It relieves at once from pain, and forming a pellicle, protects the abraded parts from the air. The *linimentum calcis* of the Pharmacopœia is equal parts of

linewater and olive oil; this is a more elegant but a less effective preparation.
See Oil.

LINT for Surgery, was formerly prepared by scraping up linen by the hand; the preparation of it, however, has been made the subject of a patent by Mr. Thomas Hoss, which consists in the employment of peculiarly constructed scrapers for abrading the surface of the linen cloth, and producing a pile or nap upon it. The scrapers are worked by a rotary motion.

Instead of rotary scrapers, a reciprocating pendulous movement is sometimes applied to a single scraper. Chisel-formed blades are claimed by the patentee as scrapers for raising the pile, by working with the bevel edges forwards, so as to scrape and not to cut the fabric. He also claims in the rotary form a ledge or bed concentric with the axis of the scraper, which he also claims; both of which seem to be serviceable. Several kinds of lint-making machines are now employed, but as they all partake more or less the above principles they do not require description.

LIQUATION (Eng. and Fr.; *Saigerung*, Germ.) is the process of sweating out, by a regulated heat, from an alloy, a more easily fusible metal, from the interstices of a metal, which is more difficult of fusion. Lead and antimony are the metals most commonly subjected to liquation: lead for the purpose of removing by its superior affinity the silver present in any complex alloy; antimony as an easy means of separating it from its combinations in the ores.

*Figs. 1138, 1139, 1140, represent the celebrated antimonial liquation furnaces of Malosse, in the department of Ardèche, in France. Fig. 1138, is a ground plan taken at the level of the draught holes *g*, *fig. 1139*, and of the dotted line *x r*; *fig. 1139*, is a vertical section through the dotted line *a n*, of *fig. 1138*; and *fig. 1140*, is a vertical section through the dotted line *c d* of *fig. 1138*. In the three figures, the same letters denote like objects. *a, b, c* are three grates upon the same level above the floor of the works, $4\frac{1}{2}$ feet long, by $10\frac{1}{2}$ inches broad; between which are two rectangular galleries, *d e*, which pass transversely through the whole furnace, and lie at a level of 12 inches above the ground. They are separated by two walls from the three fire places. The walls have three openings *f, g, h*, alternately placed for the flames to play through. The ends of these*

galleries are shut in with iron doors *i, i*, containing peep holes. In each gallery are two conical cast-iron crucibles *A A*, into which the *liquating* sulphuret of antimony drops. Their height is from 12 to 14 inches; the width of the mouth is 10 inches, that of the bottom is 6, and the thickness four-thirds of an inch. They are coated over with fire-clay, to prevent the sulphuret from acting upon them; and they stand upon cast-iron pedestals with projecting ears, to facilitate their removal from the gallery or platform. Both of these galleries are lined with tiles of fire-clay *l, l*, which also serve as supports to the vertical liquation tubes *m m*, made of the same clay. The tiles are

somewhat curved towards the middle, for the purpose of receiving the lower ends of these tubes, and have a small hole at *n*, through which the liquid sulphuret flows down into the crucible.

The liquation tubes are conical, the internal diameter at top being 10 inches, at bottom 8; the length fully 40 inches, and the thickness six-tenths of an inch. They have at their lower ends notches or slits, *a*, fig. 1140, from 3 to 5 inches long, which look outwards, to make them accessible from the front and back part of the furnaces through small conical openings *p p*, in the walls. These are closed during the operation with clay stoppers, and are opened only when the gangue, rubbish, and cinders are to be raked out. The liquation tubes pass across the arch of the furnace *q q*, the space of the arch being wider than the tubes; they are shut in at top with fire-covers *r r*, *s s*, the middle part of the arch, immediately under the middle grate, is barrel-shaped, so that both arches are abutted together. The flames, after playing round about the sides of the liquation tubes, pass off through three openings and flues into the chimney *t*, about 13 feet high; *u*, being the one opening, and *v*, the two others, which are provided with register plates. In front of the furnace is a smoke flue *w*, to carry off the sulphureous vapours exhaled during the clearing out of the rubbish and slag; another, *x*, begins over *y y*, at the top of the tubes; a wall *z*, separates the smoke flue into halves, so that the workmen upon the one side may not be incommoded by the fumes of the other. This wall connects at the same time the front flue *w* with the chimney *t*. *a' o'* and *b' b'* are iron and wooden bearer beams and rods for strengthening the smoke-flue. *c' c'* are arches upon both sides of the furnace, which become narrower from without inwards, and are closed with well fitted plates *d' d'*. They serve in particular circumstances to allow the interior to be inspected, and to see if either of the liquation furnaces be out of order. Each tube is charged with 500 lbs. of antimonial ore, previously warmed; in a short time the sulphuret of antimony begins to flow off. When the liquation ceases, the cinders are raked out by the side openings, and the tubes are charged afresh. The fused iron crucibles are allowed to become three-fourths full, are then drawn out from the galleries, left to cool and emptied. The ingot weighs about 65 pounds. The average duration of the tubes is 3 weeks. This plan is proved to be an exceedingly economical one.

LIQUEURS, LIQUORISTE. Names given by the French, and adopted into our language, to certain aromatic alcoholic cordials, and to the manufacturer of them.

Some liqueurs are prepared by infusing the woods, fruits, or flowers, in either water or alcohol, and adding thereto sugar and colouring matter. Others are distilled from the flavouring agents.

Many of the liqueurs are of very compound character, as the following recipes will show.

Martinique Noyau.—Put into a stone jar,

Preserved guavas and their syrup, or the jelly of that fruit . . .	4 lb.
Oil of sweet almonds	1 oz.
Sweet almonds, beaten fine	1
Bitter " "	1
Preserved ginger and its syrup	2
Cinnamon and cloves (bruised) of each	1
Nutmeg and Pimento " "	1
Jamaica ginger " "	1
Candied lemon and citron, of each	1
White sugar candy (powdered)	14
Proof spirit of wine	5 quarts.

Beat the oil with a little brandy, and mix it with the almonds, when beaten to a paste with orange flower water. Stop up the jar securely, and let it remain in a warm room, or in the sun, shaking it often, for a fortnight. Keep it in the jar for twelve or fifteen months; then strain it, and filter repeatedly until it is as clear as spring water. Binge phials or half pint bottles, with any white wine, drain them and fill. Cork and seal well. In six months it will be fit for use, if required, but will improve greatly by age. — Robinson.

Tears of the Widow of Malabar.—To ten pounds of spirit (pale brandy), add 4 pounds of white sugar, and 4 pints of water, adding 4 drachms of powdered cinnamon, 48 grains of cloves, and the same quantity of mace; colour with caramel.

The Sighs of Love.—Spirit, water, and sugar as above. Perfume with otto of roses, and slightly colour with cochineal.

Absinthe.—Take of the tops of wormwood, 4 pounds, root of angelica, calamus aromaticus, bruised, leaves of dittany, of each, 1 oz.; alcohol, four gallons.

Macerate these substances during eight days, add a little water, and distill by a

gents fire until two gallons are obtained. This is reduced to a proof spirit, and a few drops of the oil of aniseed added.

These forms exemplify the character of all kinds of liqueurs. They are coloured yellow by the colouring matter of *carthamus*. *Pura* is produced by caramel; red, by cochineal; violet, by limus, or archil; blue by the sulphate of indigo; green, by mixing the blue and the yellow together.

Ratafia is the generic name, in France, of liqueurs compounded with alcohol, sugar, and the odoriferous or flavouring principles of vegetables. Bruised cherries with their stones are infused in spirit of wine to make the *ratafia* of *Grenoble de Trévaders*. The liquor being boiled and filtered, is flavoured, when cold, with spirit of *myrica*, made by distilling water off the bruised bitter kernels of apricots, and mixing it with alcohol. Syrup of bay laurel and galango are also added.

LIQUID AMBAR. See *AMBAR*. *Liquor*.

LIQUORICE (*Glycyrrhiza Officinalis*; from *glychs*, sweet, and *rhiza*, a root). The root only is employed; these roots are thick, long, and running deep in the ground.

Besides the use of liquorice roots in medicine, they are also employed to brewing, and are pretty extensively grown for these purposes in some parts of England. Liquorice requires a rich deep dry sandy soil, which, previous to forming a new plantation, should be trenched to the depth of about three feet, and a liberal allowance of manure regularly mixed with the earth in trenching. The plants which are procured by slipping them from those in old plantations are, either in February or March, dibbled in rows three feet apart, and from eighteen inches to two feet in the row. They require three summers' growth before being fit for use, when the roots are obtained by retrenching the whole, and they are then stored in sand for their preservation until required. — *Peter Lawson*.

LITHARGE (Eng. and Fr.; *Glätte*, Germ.) is the fused yellow protoxide of lead, which on cooling passes into a mass consisting of small six-sided plates, of a reddish yellow colour and semitransparent. It generally contains more or less red lead, whence the variations of its colour, and carbonic acid, especially when it has been exposed to the air for some time. See **LEAD** and **SULPHUR**, for its mode of preparation.

LITHIA is a simple earthy or alkaline substance, discovered in the minerals called petalite and triphane. It is white, very caustic, reddens litmus and red cabbage, and saturates acids with great facility. When exposed to the air it attracts humidity and carbonic acid. It is more soluble in water than baryta; and has such a strong affinity for it as to be obtained only in the state of a hydrate. It forms neutral salts with all the acids. It is most remarkable for its power of acting upon or corroding platinum.

LITHIUM is the metallic basis of lithia; the latter substance consists of 100 of metal, and 123 of oxygen. Neither lithium nor its oxide are of any use in the arts.

LITHOGRAPHIC PRESS. The lithographic press in common use has long been regarded as a very inadequate machine. The amount of manual power required to work it, and the slow speed at which, under the most favourable circumstances, copies can be produced, disables lithography in its competition with letter-press. A career of brilliant success has attended the efforts of scientific men towards speed and perfection in this latter branch of the art; and the present printing machines surpass the hand-press somewhat in the same ratio as does our express speed the jog-trot of our forefathers. The engravings annexed, *figs.* 1141, 1142, will serve to illustrate Messrs. Napier & Sons' improvements upon the lithographic press. The machine is arranged to be driven by steam power; has belts, "crossed" and "open," supposed to be in connection with the engine, and to run upon the pulleys A, B, C. The crank pulley, A, is fixed on the screw-spindle D, and the other two work loose, or "dead," on the same spindle; these bands with their striking forks, G, are arranged so as to be brought alternately upon the fixed pulley G, and thus a reversing motion is given to the screw. The nut in which the screw works is fixed to a crosspiece R, which braces the side frames T T, together at bottom, while the bar C, performs the same office at top; the scraper-box, H, is sustained between

these frames at bearings *t*, and is so fitted as to work freely. To support the frames and scraper-box independent of the screw and maintain them in

1142

position, allowing freedom of action, the rollers *z, z*, are provided, which run in the planed recesses, *x*, along the top of the main standards *l*.

The machine is shown with its tympan down, ready for starting: this is effected by pressing lightly upon the lever, *b*, which raises a catch, and allows the weight *m*, to descend in the direction of its present inclination, and act upon the connections with the striking forks, so as to bring one of the bands upon the fast pulley, *n*, and make the scraper and its frames move forward. The return is caused by the frame, *r*, coming in contact with a stop *c*, which, yielding, acts upon the striking forks by its bar *d*, upon which it may be adjusted to give the travel required. On the return being accomplished, the machine stops itself by a striking action against stop *e*, the catch *b* falling in to prevent the weight descending to its full throw, and thus retaining the two bands upon the two dead pulleys, *a* and *c*, while the machine is prepared for another impression.

The action of the scraper is peculiar and novel: it is balanced, so that its tendency is to remain slightly raised, but in its forward movement, and at the point desired, it is made to descend by a stop fixed upon the top of the main standard, *l*, into a position vertical, or nearly so, in which position it is retained by its own onward progress against strong abutments projecting from the frames, *r*; on the return it resumes its raised position and passes back without impediment. The scraper may be adjusted to give the pressure desired, or the table on which the stone is placed regulated by screws.

The advantages embodied in this machine will be at once recognised by those interested. The pulling down of the scraper, and the labour and inconvenience attendant upon that operation, are entirely superseded by the simple and effectual valve-like movement just explained, which forms the ground work of this combination, although it will alike apply to the press work by hand, and is the most striking novelty in the machine.

LITHOGRAPHY. Though this subject belongs rather to the arts of taste and design than to productive manufactures, its chemical principles fall within the province of this Dictionary.

The term *lithography* is derived from *λίθος*, a stone, and *γραφω*, writing, and designates the art of throwing off impressions upon paper of figures and writing previously traced upon stone. The processes of this art are founded:—

1. Upon the adhesion to a grained or smoothly-polished limestone, of an encaustic fat which forms the lines or traces.
2. Upon the power acquired by the parts penetrated by this encaustic, of attracting to themselves, and becoming covered with, a printer's ink, having linseed oil for its base.
3. Upon the interposition of a film of water, which prevents the adhesion of the ink in all the parts of the surface of the stone not impregnated with the encaustic.
4. Lastly upon a pressure applied to the stone, such as to transfer to paper the greater part of the ink which covers the greasy tracings or drawings of the encaustic.

The lithographic stones of the best quality are still procured from the quarry of Solenhofen, a village at no great distance from Munich, where this mode of printing had its birth. They resemble in their aspect the yellowish-white lias of Bath, but their geological place is much higher than the lias. Abundant quarries of these fine-grained limestones occur in the county of Huppenheim, along the banks of the Danube, presenting slabs of every required degree of thickness, parted by regular seams, and ready

for removal with very little violence. The good quality of a lithographic stone is generally denoted by the following characters: its hue is of a yellowish grey, and uniform throughout; it is free from veins, fibres, and spots; a steel point makes an impression on it with difficulty; and the splinters broken off from it by the hammer display a conchoidal fracture.

The Munich stones are retailed on the spot in slabs or layers of equal thickness; they are quarried with the aid of a saw, so as to sacrifice as little as possible of the irregular edges of the rectangular tables or plates. One of the broad faces is then dressed, and coarsely smoothed. The thickness of these stones is nearly proportional to their other dimensions; and varies from 1½ inches to 3 inches.

In each lithographic establishment, the stones receive their finishing, dressing, and polishing; which are performed like the grinding and polishing of mirror plate. The work is done by hand, by rubbing circularly a movable slab over another in a horizontal position, with fine sifted sand and water interposed between the two. The style of work that the stone is intended to produce determines the kind of polish that it should get. For crayon drawing the stone should be merely grained more or less *fine* according to the fancy of the draftsman. The higher the finish of the surface the softer are the drawings; but the printing process becomes sooner *gummy*, and a smaller number of impressions can be taken. Works in ink require the stone to be more softened down, and finally polished with pumice and a little water. The stones thus prepared are packed for use with white paper interposed between their faces.

Zinc plates are sometimes used in lieu of stones; they are prepared by graining the surface with fine sand, rubbed over by means of a small piece of the metal. Zinc takes a finer surface than stone, and yields more delicate impressions; but great care is necessary in keeping it dry, so that it does not corrode; this is almost the only objection to its more general use, for it is far more convenient to handle and move about than heavy stones.

Lithographic crayons.—Fine lithographic prints cannot be obtained unless the crayons possess every requisite quality. The ingredients composing them ought to be of such a nature as to adhere strongly to the stone, both after the drawing has undergone the preparation of the acid, and during the press-work. They should be hard enough to admit of a fine point, and trace delicate lines without risk of breaking. The following composition has been successfully employed for crayons by MM. Bernard and Delarue, at Paris:—

Pure wax (first quality)	-	-	-	-	4 parts.
Dry white tallow soap	-	-	-	-	2 "
White tallow	-	-	-	-	2 "
Gum lac	-	-	-	-	2 "
Lamp black, enough to give a dark tint	-	-	-	-	1 "
Occasionally copal varnish	-	-	-	-	1 "

The wax should be melted over a gentle fire, and the lac, broken to bits, is then added by degrees, stirring all the while with a spatula; the soap is next introduced in fine shavings; and when the mixture of these substances is very intimately accomplished, the copal-varnish, incorporated with the lamp black, is poured in. The heat and agitation are continued till the paste has acquired a suitable consistence; which may be recognised by taking out a little of it, letting it cool on a plate, and trying its quality with a penknife. This composition, on being cut, should afford brittle slices. The boiling may be quickened by setting the rising vapours on fire, which increases the temperature, and renders the exhalations less offensive. When ready, it is to be poured into a brass mould, made of two small cylinders joined together by clamps or rings, forming between them a cylindric tube of the crayon size. The mould should be previously rubbed with a greasy cloth.

The soap and tallow are to be put into a small goblet and covered up. When the while is thoroughly fused by heat, and no clots remain, the black is gradually sprinkled in with careful stirring.

Lithographic ink is prepared nearly on the same principle:—

Wax	-	-	-	-	-	16 parts
Tallow	-	-	-	-	-	6 "
Hard tallow soap	-	-	-	-	-	6 "
Shell-lac	-	-	-	-	-	12 "
Mastic in tears	-	-	-	-	-	8 "
Venice turpentine	-	-	-	-	-	10 "
Lamp black	-	-	-	-	-	4 "

The mastic and lac, previously ground together, are to be carefully heated in the turpentine; the wax and tallow must be added after they are taken off the fire and when their solution is effected, the soap shavings are to be thrown in. Lastly, the lamp

black is to be well intermixed. Whenever the union is accomplished by heat the operation is finished; the liquor is left to cool a little, then poured out on tables, and, when cold, cut into square rods.

Lithographic ink of good quality ought to be susceptible of forming an emulsion so attenuated, that it may appear to be dissolved when rubbed upon a hard body in distilled or river water. It should flow in the pen, but not spread on the stone; capable of forming delicate traces, and very black, to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to reproduce the most delicate outlines of the drawing, and to afford numerous impressions. It must therefore be able to resist the acid with which the stone is moistened in the preparation, without letting any of its greasy matter escape.

M. de Lasterrie states that after having tried a great many combinations, he gives the preference to the following:—

Tallow soap dried	-	-	-	30 parts.
Mastic in tears	-	-	-	30 ..
White soda of commerce	-	-	-	30 ..
Shell-lac	-	-	-	150 ..
Lamp-black	-	-	-	12 ..

The soap is first put into the goblet and melted over the fire; the lac being added it fuses immediately; the soda is then introduced, and next the mastic, stirring all the while with a spatula. A brisk fire is applied till all these materials are melted completely, when the whole is poured out into the mould.

The inks now prescribed may be employed either with the pen and the hair pencil, for writings, black-lead drawings, *aqua tinta*, mixed drawings, those which represent engravings on wood (woodcuts), &c. When the ink is to be used it is to be rubbed down with water, in the manner of China ink, till the shade be of the requisite depth. The temperature of the place ought to be from 84° to 90° Fahr., or the saucer in which the ink stick is rubbed should be set in a heated plate. No more ink should be dissolved than is to be used at the time, for it rarely keeps in the liquid state for 24 hours; and it should be covered or corked up.

Autographic paper.—Autography, or the operation by which a writing or a drawing is transferred from paper to stone, presents not merely a means of abridging labour, but also that of reversing the writings or drawings into the direction in which they were traced, whilst, if executed directly upon the stone, the impression given by it is inverted. Hence, a writing upon stones must be inverted from right to left to obtain direct impressions. But the art of writing thus is tedious and difficult to acquire, while, by means of the autographic paper and the transfer, proofs are obtained in the same direction with the writing and drawing.

Autographic ink.—It must be fatter and softer than that applied directly to the stone, so that though dry upon the paper, it may still preserve sufficient viscosity to adhere to the stone by mere pressure.

To compose this ink, we take—

White soap	-	-	-	100 parts.
White wax of the best quality	-	-	-	100 ..
Mutton suet	-	-	-	30 ..
Shell-lac	-	-	-	50 ..
Mastic	-	-	-	50 ..
Lamp black,	-	-	-	30 or 35 ..

These materials are to be melted as above described for the lithographic ink.

Lithographic ink and paper.—The following recipes have been much commended:—

Virgin or white wax	-	-	-	8 parts.
White soap	-	-	-	2 ..
Shell-lac	-	-	-	2 ..
Lamp black	-	-	-	3 table-spoonfuls.

Preparation.—The wax and soap are to be melted together, and before they become so hot as to take fire, the lamp black is to be well stirred in with a spatula, and then the mixture should be allowed to burn for 30 seconds; the flame being extinguished, the lac is added by degrees, carefully stirring all the time; the vessel is to be put upon the fire once more in order to complete the combination, and till the materials are either kindled or nearly so. After the flame is extinguished, the ink must be suffered to cool a little, and then put into the moulds.

With the ink crayons thus made, lines may be drawn as fine as with the point of the graver, and as full as can be desired, without risk of its spreading in the carriage. Its traces will remain unchanged on paper for years before being transferred.

Some may think it strange that there is no suet in the above composition, but it has

been found that ink containing it is only good when used soon after it is made, and when immediately transferred to the stone, while traces drawn on paper with the same ink become defective after 4 or 5 days.

Lithographic paper.—Lay on the paper 3 successive coats of sheep-foot jelly, 1 layer of white starch, 1 layer of gamboge.

The first layer is applied with a sponge dipped in the solution of the hot jelly, very equally over the whole surface, but thin; and if the leaf be stretched upon a cord, the gelatine will be more uniform. The next two coats are to be laid on, until each is dry. The layer of starch is then to be applied with a sponge, and it will also be very thin and equal. The coat of gamboge is lastly to be applied in the same way. When the paper is dry, it must be smoothed by passing it through the lithographic press; and the more polished it is, the better does it take on the ink in fine lines.

Transfer—When the paper is moistened, the transfer of the ink from the gamboge is perfect and infallible. The starch separates from the gelatine, and if, after taking the paper off the stone, we place it on a white slab of stone, and pour hot water over it, it will resume its primitive state.

The coat of gamboge ought to be laid on the same day it is dissolved, as by keeping it becomes of an oily nature; in this state it does not obstruct the transfer, but it gives a gloss to the paper which renders the drawing or tracing more difficult, especially to persons little accustomed to lithography.

The starch paste can be employed only when cold, the day after it is made, and after having the skin removed from its surface.

A leaf of such lithographic paper may be made in two minutes.

In transferring a writing, an ink drawing, or a lithographic crayon, even the impression of a copper-plate, to the stone, it is necessary, 1. that the impressions be made upon a thin and slender body like common paper; 2. that they may be detached and fixed totally on the stone by means of pressure; but as the ink of a drawing sinks to a certain depth in paper, and adheres rather strongly, it would be difficult to detach all its parts, were there not previously put between the paper and the traces a body capable of being separated from the paper, and of losing its adhesion to it by means of the water with which it is dampened. In order to produce this effect, the paper gets a certain preparation, which consists in coating it over with a kind of paste ready to receive every delineation without suffering it to penetrate into the paper. There are different modes of communicating this property to paper.

Besides the above, the following may be tried. Take an unsized paper, rather strong, and cover it with a varnish composed of:—Starch, 120 parts; gum arabic, 40 parts; alum, 20 parts.

A paste of moderate consistence must be made with the starch and some water, with the aid of heat, into which the gum and alum are to be thrown, each previously dissolved in separate vessels. When the whole is well mixed, it is to be applied, still hot, on the leaves of paper, with a flat smooth brush. A tint of yellow colour may be given to the varnish with a decoction of the berries of Avignon, commonly called French berries by our dyers. The paper is to be dried, and smoothed by passing under the scraper of the lithographic press.

Steel pens are employed for writing and drawing with ink on the lithographic stones; in many establishments a sable brush is more frequently used.

Engraving on stone, for maps, geometrical drawings of every kind, patent inventions, machinery, &c., is performed with a diamond point as clearly and distinctly as if executed on copper or steel plates; to print these engraved stones, the ink should be laid on with a dabber, not a roller. Another method is by preparing the surface of the stone with a thin covering, or etching ground, of gum and black, upon which the design is traced or engraved with an etching point; it then appears in white lines upon a black surface. In this state the stone is taken to the printer, who applies ink to the engraved part, and washing off the gum, the drawing appears in black lines upon the white surface of the stone, and after being submitted to the process of fixing, described below, is ready for printing.

Litholat, a process of drawing upon stone was adopted, first, by Mr J. D. Harding, a few years back; and since by one or two other artists; several works were at the time executed by this method, which consists in painting the subject with a camel hair pencil, dipped in a preparation of liquid lithographic chalk, using the latter as if it were an ordinary colour, or Indian ink, sepia, &c. The results of this process were, however, so uncertain in printing, that it has been almost, if not entirely, abandoned.

The process of printing a subject executed in lithography is as follows.—The drawing is first executed by the artist on the stone in as perfect and finished a manner as if done on paper or card-board; the stone is then washed over with nitric acid, diluted with gum, which neutralises the alkali, or soap, contained in the chalk,

fixes the drawing, and cleanses the stone at the same time: this is technically called *etching*. The acid is then washed off with cold water, and any particles of the crayon or other substances which may have adhered to the surface, are removed by the application of a sponge dipped in spirits of turpentine: the stone is now ready for printing. It is slightly wetted, charged with printing-ink by means of a roller, the sheet of paper, which is to receive the impression, is laid on it in a damp state, and the whole is passed through the press.

Chromolithography, or printing in colours from stones (*χρῶμα*, colour) is a comparatively recent introduction, but has been brought to such perfection, that works of art of the highest pictorial excellence are sometimes so closely imitated, as to deceive very competent judges. A portrait of Shakspeare, for example, executed in chromolithography by Mr. Vincent Brooks, of London, from an old oil painting, is so marvellous a copy of the original as almost to defy detection. Chromolithography, as a beautiful medium of illustration, is now in very general use: the process may be thus described. A drawing of the subject, in outline, on transfer tracing-paper, is made in the ordinary way when transferred to a stone, this drawing is called the *égoutte*, and it serves as a guide to all the others, for it must be transferred to as many different stones as there are colours in the subject; as many as thirty stones have been used in the production of one coloured print. The first stone required, generally for flat, local tints, is covered with lithographic ink where the parts should be of solid colour: the different gradations are produced by rubbing the stone with *rubbing-stuff*, or tint-ink, made of soap, shell lac, &c. &c., and with a painted lithographic chalk where necessary; the stone is then washed over with nitrous acid, and goes through the entire process described above. A roller charged with lithographic printing-ink is then passed over it to ascertain if the drawing comes as desired; and the ink is immediately afterwards washed off with turpentine: if satisfactory, this stone is ready for printing, and is worked off in the requisite colour; the next stone undergoes the same process for another colour, and so with the rest till the work is complete: it will of course, be understood, that before any simple impression is finished, it will have to pass through as many separate printings as there are drawings on stones. The colours used in printing are ground up with burnt linseed oil, termed *varnish*. — J. D.

LITHOMARGE. A silicate of alumina, in many respects resembling China clay or kaolin, *whence see*.

LITMUS (*Tournefort, Fr.; La Lina, Germ.*) is prepared in Holland from the species of lichen called *Lecanora tartarea*, *H. in tartarea*. The ground lichens are first treated with urine containing a little potash, and allowed to ferment for several weeks, whereby they produce a purple-red; the coloured liquor, treated with quicklime and some more urine, is set again to ferment during two or three weeks, then it is mixed with chalk or gypsum into a paste, which is formed into small cubical pieces by being pressed into brass moulds, and dried in the shade. Litmus has a violet-blue colour, is easy to pulverise, is partially soluble in water and dilute alcohol, leaving a residuum consisting of carbonate of lime, of clay, silica, gypsum, and oxide of iron combined with the dye. The colour of litmus is not altered by alkalis, but is reddened by acids; and is therefore used in chemistry as a delicate test of acidity, either in the state of solution or of unsized paper stained with it. See **LICHEN**.

The preparation of litmus has been described by Ferber, Morriox, and others.

Dr. Percival writes, "Litmus is imported from Holland, in the form of small, rectangular, light, and friable cakes of an indigo blue colour. Examined by the microscope, we find sporules and portions of the epidermis and mesothallus of some species of lichen, mixed with sand, &c. The colour of the cakes is that of indigo and violet. The violet odour is acquired while the mixture is undergoing fermentation, and is common to all the tinctorial lichens. It has led some writers into the error of supposing that the litmus makers use Florentine orris in the manufacture of litmus. The indigo colour depends on the presence of indigo in the litmus cakes."

LITMUS PAPER. Paper coloured with an infusion of litmus, used as a test for the presence of acids.

Faraday, in his *Chemical Manipulation*, recommends an infusion of one ounce of litmus, and half a pint of hot water. Rhetorical paper is saturated with this. Professor Graham prefers good letter paper to the unsized paper. In order to obtain very delicate test-paper, the alkali in the litmus must be almost neutralised by a minute portion of acid.

LITTORAL (a geological term). Belonging to the sea-shore.

LIVI-DIVI. Another name for Divi-divi. See **LEATHER**.

LIXIVIATION (*Lixivage, Fr.; Auslügen, Germ.*) signifies the abstraction by water of the soluble alkaline or saline matters present in any earthly admixture; as from that of quicklime and potashes to make potash lye, from that of effloresced alum schist to make aluminous liquors, &c.

LLAMA. A genus of animals belonging to the class *Mammalia*, order *Ungulata*, family *Bovidae*, and tribe *Camelina*. They are the camels of South America, to which country they are confined. In the wild state the llamas keep together in herds of from one to two hundred. There are two distinct species found wild in South America, inhabiting the Peruvian Alps, the Panipaa, and the mountains of Chili. These animals are used as beasts of burden; cords and sacks, as well as stuffs for ponchos, &c., are fabricated from their wool; and their bones are converted into instruments for weaving the same. The Alpaca, which is a variety of the llama, has given its name to a cloth manufactured from its hair; and this has become so valuable, that attempts have been made to naturalise the animal in Europe. The success, however, which has attended these attempts has not been great. The following note from the *Penny Cyclopædia*, article *Llama*, is important.

"In reference to the wool, we may here state that a herd of thirty-six, including the kinds called llamas, alpacas, and vicuñas or viconias, were sent from Lima (Peru) and Concepcion (Chili) to Buenos Ayres by journeys of two or three leagues. In those who may be inclined to import these animals, it may be necessary to state that they were fed during the journey with potatoes, malae, and hay. As soon, however, as the potatoes were exhausted, constipation came on so obstinately, that medical relief was required. They were shipped as a present from Godoy, the Prince of Peace, to the Empress Josephine, but only eleven arrived at Cadiz in 1808, just as Godoy fell into disgrace. More two died, and the rest were near being thrown into the sea by the infuriated rabble, in their detestation of the late minister and minion. The poor llamas were however saved from the tender mercies of the populace by the governor of Cadiz, and were consigned to Don Francisco de Tberan of Andalusia, who had a fine menagerie at San Lúcar de Barrameda. When the French occupied the province, Marshal Soult protected them; and M. Dury St. Vincent, who was with the army, studied their habits, and executed drawings of them, which were lost at the battle of Vittoria. M. Dury paid great attention to their wool, and some from each kind was sent to the Academy of Sciences at Paris. From the report of the French naturalist and the philosophical Spaniard, it would appear that the fleece of the alpa-viconia (produced by a cross between a viconia and an alpaca) has much greater length than any other variety, and is six times heavier."

The following is from *James's History of the Woollen Manufacture in England*, p. 662:—

To commence with the earliest mention of the alpaca, we must recur to so early a period as the year 1525, when Pizarro and his ferocious companions invaded Peru. It is related by the Spanish historians, that they found there four varieties of sheep; two, the guanaco and the vienna, in a wild state, ranging the mountainous tracts of South America; and the others, the llama and the paco, or alpaca, domesticated. The former of these domestic animals, partaking somewhat of the nature and size of the Arabian camel, was in like manner employed as a beast of burden. Though in many features similar to the llama, the alpaca had several clear marks of distinction, and among others was less, and the fleece much longer and softer in fibre. In the sixteenth century, and even from the remotest times, the Peruvians being comparatively (to the other tribes of the great continent of America) a civilised people, and well acquainted with the arts of spinning and weaving, fabricated from alpaca wool textures of much delicacy and beauty, which were highly prized as articles of dress. And that the use of them had prevailed for centuries is demonstrated by the opening of several very ancient tombs of the Peruvians, in which the dead had been enwrapped in stuffs made from the fleece of the alpaca.

In general, the alpaca ranges about four feet in height, the size of a full grown deer, and, like it, is of graceful appearance. Its fleece is superior to the sheep in length and softness, averaging six inches (the length of the staple of the alpaca fleece is on an average much less than formerly, probably from being shorn oftener), and sometimes it has been procured even of an extraordinary length; a specimen shown at the Great Exhibition, by Messrs. Walter Milligan and Son, reaching to forty-two inches in length. The fleeces, when annually shorn, range from five to six pounds. Contrary to experience in other descriptions of wool, the fibre of the Alpaca fleeces acquires strength without coarseness; besides, each filament appears straight, well formed, and free from crispness, and the quality is more uniform throughout the fleece. There is also a transparency, a glittering brightness upon the surface, giving it the glossiness of silk, which is enhanced on its passing through the dye-vat. It is also distinguished by softness and elasticity, essential properties in the manufacture of fine goods, being exempt from spiral, curly, and shaggy defects; and it spins, when treated properly according to the present improved method, easily, and yields an even, strong, and true thread. With all these remarkable qualities, it was long before the value of alpaca wool was known or appreciated in this country.

Recurring to the application of the alpaca fleece to manufacturing purposes in England, it was long delayed. Though so early as the year 1807, the British troops returning from the attack of Buenos Ayres brought with them a few bags of this wool, which were submitted for inspection in London; but, observes Walton in his work on alpaca, "owing to the difficulty of spinning it, or the prejudice of our manufacturers, it did not then come into notice," and for more than twenty years the attempt does not seem to have been renewed; thus depriving, for that period, the country of the advantage derived from this notable manufacture.

According to the best authorities, the first person in England who introduced a marketable fabric made from this material was Mr. Benjamin Cutram, a scientific manufacturer of Greetland, near Halifax, who, about the year 1830, surmounted, with much difficulty, the obstacles encountered in spinning the wool, and eventually produced an article which sold at high prices for ladies carriage shawls and cloakings; but their value arose more from being rare and curious articles than from intrinsic worth.

These were, it is well established, quite destitute of the peculiar gloss and beauty which distinguish the alpaca lustrous and fabrics of later times, and after a short period the manufacture was abandoned.

About the same time as Mr. Cutram was weaving goods from alpaca, the wool attracted the notice of the Bradford spinners. Messrs. Wood and Walker spun it to some extent for camelot warps used in the Norwich trade. Owing to the cheapness of alpaca wool during the first years of its consumption in England, it was occasionally employed instead of English long wool for preparing lasting and camelot warps, being spun to about No 48.

The earliest manufacture of the alpaca wool into goods at Bradford appears to have occurred under these circumstances. In the commencement of 1832 some gentlemen, connected with the trade to the west coast of South America, were on a visit at the house of J. Garnett, Esq., of Clithero, and, on their alluding to the difficulty of meeting with suitable returns for goods forwarded to that part of the world, he suggested to them the transmission of alpaca wool, and offered, if they would send him a few pounds weight, to ascertain its value for manufacturing purposes. In a few months he received some samples of alpaca wool, which, on the 2nd of October, 1832, he forwarded to Messrs. Horsfall, of Bradford, with a request that they would test its value. Accordingly they fabricated from this wool a piece resembling heavy camelot, which they showed to the Leeds merchants; but the piece, not developing any peculiar qualities of alpaca, did not please, so that Messrs. Horsfall were not encouraged to proceed further with experiments. However, in the same year Messrs. Hyam, Hall, and Co., spirited merchants of Liverpool, perceiving the value of the alpaca wool, directed their agents in Peru to purchase and ship over all the parcels of alpaca wool they could meet with; some of which, being sent to the Bradford district, was spun and manufactured by several parties there. The pieces chiefly fabricated from alpaca in the neighbourhood of Bradford were figures made with worsted warp and alpaca weft, the figure being raised and lustrous like union damasks. These goods were in vogue for a limited time, for neither the figured nor plain ones seem to have suited the public taste.

Until the introduction of cotton warps into the worsted trade, it may safely be asserted that the alpaca manufacture had not been developed, and would never have made much progress without being combined with cotton or silk warp. To Titus Salt, Esq., of Bradford, most undoubtedly be awarded the high praise of finally overcoming the difficulties of preparing and spinning the alpaca wool so as to produce an even and true thread, and, by combining it with cotton warps, which had then (1836) been imported into the trade of Bradford, improved the manufacture so as to make it one of the staple industries of the kingdom. He has, by an admirable adaptation of machinery, been enabled to work up the material with the ease of ordinary wool, and thus present beautiful alpaca stuffs at a reasonable rate. Every previous attempt had been made, so far as can be ascertained, with worsted warps, with which the alpaca did not easily assort.

About the year 1836 the alpaca trade had become established, and has since risen to much importance. After this period the manufacture rapidly extended. The great mercantile house of A. and S. Henry took very large quantities of alpaca stuffs, which began to be made in an endless variety of goods suited both for male and female dress, including scarfs, handkerchiefs, and cravats, plain and figured goods, both with silk and cotton warp, for ladies' dresses, dyed alpaca checks of beautiful texture, and a variety of gingham, cordingtons, silk-striped, checked, and figured alpacas and alpaca linings. The demand for these various alpaca fabrics during the period between 1831 and 1846 remained uniform and steady.

At the commencement of the manufacture of alpaca goods with cotton warps (silk

was not used), the web was spun from fine qualities of the wool into low numbers, and the pieces were made much richer and heavier than has been the case more recently, the demand having altered in favour of lighter and less costly cloth.

Most of the alpaca wool brought into the United Kingdom is unshipped at Liverpool, but a small portion is also carried to London. At these two ports, it may be asserted, the whole imported into this country is landed. It arrives in small bales, called ballots, weighing about seventy pounds, and is generally in an impure state, with different qualities mixed. Like the fleece of the sheep, that of the alpaca is composed of different qualities, so that the portion growing on the hind quarters is of an inferior description. The wool is sorted into about eight different qualities, each fitted for a particular class of goods. Owing to the dirty state of the fleeces, and the peculiar nature of the dusty particles arising during the progress of sorting, the operation is an unhealthy one, unless great care be taken by ventilation to counteract this baneful effect. After being sorted, it is at Saltaire washed and combed by machinery. Until of late years it was combed wholly by hand, and the combs used for the purpose were of a deeper pitch than those usually adopted for preparing sheep's wool, that is, those combs had a larger number of teeth than ordinary. The next process is to draw the sliver, which is perfected by an improved gill machine, especially adapted for this material. And here, in combing and preparing the alpaca wool, so as to make a clean, even, and glossy thread, lay the grand difficulty in the way of applying the alpaca fibre to the worsted manufacture, and which was so successfully surmounted by Mr. Salt.

The main articles now manufactured from alpaca wool consist of alpaca lustras, which are dyed, and alpaca mixtures, which are undyed, and both are made of cotton or silk warp. These plain goods may from their extensive and steady use be termed stock articles. Large quantities of fancy alpacas are made, but they are rapidly varying and are distinguished by innumerable names. The material is at present much shorter in staple than formerly, owing to the alpaca being shorn oftener, so that it is now commonly from five to eight inches in length. Nearly all the alpaca wool consumed in England is worked up in the Bradford district.

Dating from the year 1834, when the importation of alpaca wool sprung up as a permanent branch of commerce, the demand in this country has, with the exception of the last two years, on the whole been a growing one. Mr. Walton, in his work on the alpaca, exhibits the quantities exported chiefly to England until the year 1843, when the tariff law having come into operation, the returns began to be more correctly framed, and the alpaca wool was then classed by itself.

Years.	Lbs.	Years.	Lbs.
1834	5,700	1839	1,215,000
1835	194,400	1840	1,650,000
1836	199,000	1841	1,541,000
1837	385,400	1842	1,443,200
1838	459,300		

In the interval of these twelve years, the price had, with the demand, progressively increased: the price in 1834 only amounted to about eightpence halfpenny per pound; next year it reached nearly tenpence; the year after one shilling; in 1838, to upwards of one shilling and threepence halfpenny; and in 1839, to one shilling and fourpence per pound.

Since the year 1842, the returns of alpaca wool imported into this country are of a more reliable character. The following table has been drawn up from data furnished by the Board of Trade.

Years.	Lbs.	Years.	Lbs.
1843	1,458,002	1850	1,659,793
1844	635,357	1851	2,013,303
1845	1,261,905	1852	2,064,894
1846	1,554,257	1853	2,148,267
1848	1,521,370	1854	1,967,513
1849	1,655,300	1855	1,446,707

Astonishing as it may appear, the bulk of these importations have been consumed in England, and the quantity re-shipped to the Continent has been comparatively trifling in amount.

During the last ten years, the prices have fluctuated considerably. In 1844, one shilling and eightpence per pound was quoted as the price of the white fleece, and two shillings for the black one. In the year 1855, according to the price currents, the average rates were thus quoted :

	s.	d.	s.	d.
Alpaca, best white	-	-	3	6 to 2 8
Idio, brown and black	-	-	2	6 " 2 8
Vicuna, best dark coloured	-	-	3	0 " 3 6
Llama	-	-	0	10½ " 1 3

But these quotations are undoubtedly higher for alpaca wool than the prices realised, which of late years have ranged from two shillings and twopence to two shillings and sixpence per pound.

LOAD. A burthen or freight. As the various quantities of material contained in a load cannot but be useful, the following table is borrowed from *Mr. P. L. Simmonds' "Trade Products,"* &c.

Corn	-	3 qrs. or 40 bushels.	Coffee, in bags	-	12 cwt.
Straw	-	36 trusses or 11 cwt. 66 lbs.	Hice	-	10 cwt.
Old hay	-	16 cwt.	Timber—		
New hay	-	12 cwt. 32 lbs.	1 inch plank	-	600 square feet.
Bricks	-	500.	1½ inch "	-	400 " "
Tiles	-	1000.	2 inch "	-	300 " "
Lead ore (in Derbyshire) 2 dishes or nearly 3 cwt.			2½ inch "	-	240 " "
Batrabes	-	63 bundles.	3 inch "	-	200 " "
Mortar	-	27 feet.	3½ inch "	-	170 " "
			4 inch "	-	150 " "

LOADSTONE, MAGNETIC IRON-STONE. (*Fer aspidul.* Fr.; *Magnetstein*, Germ.) An iron ore consisting of the protoxide and peroxide of iron in a state of combination.

It was first discovered in Magnesia, and from that province has been derived the name *Magnet* applied to this ore of iron. The term loadstone, however, is given to those specimens which are powerfully magnetic only. A considerable number of the igneous rocks containing iron are magnetic, and many magnetic oxides of iron are found in England, especially near Penryn in Cornwall, near Brent in Devonshire, at Rusedale in Yorkshire, and some other places. See *Iron*.

LOAM. (*Terre limoneuse*, Fr.; *Lehm*, Germ.) A native clay mixed with quartz sand and iron ochre, and occasionally with some carbonate of lime.

" More commonly we find sand and clay or clay and marl intermixed in the same mass. When the sand and clay are each in considerable quantities, the mixture is called 'loam.'—*Lyell*.

LOCKS. Although locks are distinctly a manufacture, yet they were not embraced in former editions of this work, the chief cause of this being the desire on the part of Dr. Ure to limit the articles of the dictionary to such manufactures as were not comprehended within his meaning of the term handicraft.

The lock manufacture is essentially one of handicraft, and seeing that these volumes could not possibly enter into any detailed description of this and numerous other trades, as watchmaking and the like, it has been determined that a brief notice of the several kinds of locks alone shall find a place in its pages.

The lock manufacture of this country is confined almost exclusively to Wolverhampton and the neighbouring village of Willenhall. There are very few large manufactories, almost all kinds of locks being made by small masters, employing from nearly a dozen to a dozen men.

In half a every kind of lock, a bolt shoots out from the box or lock, usually of an oblong shape, and catches in some kind of staple or box fixed to receive it. In some a staple enters the lock, and the bolt passes through the staple within the lock. The lock of a room door is of the first character. The lock of a writing desk or ordinary box, is of the second kind. The key is merely a bent piece of iron which, on entering the lock, can move freely and push forward the bolt. To the bolts of superior locks springs are attached, and the force required to turn the key in a lock is the force necessary to overcome the resistance of the springs. The following two figures, 1143, 1144, represent the character of a lock with wards or wheels which are introduced to give safety. Fig. 1143 is an ordinary back spring lock, representing the bolt half shot; a' a' are notches on the under side of the bolt connected by a curved

portion; *b* is the back spring, which is of course compressed as the curved portion of the bolt passes through the aperture prepared for it in the rim of the lock; when

1144

1143

the bolt is withdrawn, the notch *c* rests in the rim; when the bolt is shot, the notch *a* rests in the same manner. The action of the key and wards is shown in fig. 1144. The curved pieces of metal are the wards; and there are two clefts in the bit of the key to enable it to move without interruption.

The tumbler lock is shown in its most simple form in fig. 1145. Here the bolt has two slots *a a* in the upper part; and behind the bolt is a kind of latch *b* which carries a projecting piece of metal; *c*, this is the tumbler which moves freely on a pivot at the other end. When the bolt is fully shot the projecting piece of metal falls into one notch; and when withdrawn, it falls into the other. It will be evident here that the action of the key is to raise the tumbler, so that the bolt has free motion; this action will be intelligible by tracing the action of the key on the dotted lines. These tumbler locks are greatly varied in character; but in principle they are as above described. Numerous well known locks have been patented, the most remarkable being Chubb's lock, which has been fully described by the inventors in a paper read before the Institution of Civil Engineers; and also in an excellent treatise on locks to be found in Mr. Weale's series of useful manuals. This lock is essentially a tumbler lock, it being fitted up with no less than six tumblers; and the key has to raise by a series of steps these, before the bolt is free to move. It will be obvious, that unless the key is exactly fitted to move these, there is no chance of moving the bolt. In his paper already alluded to, Mr. Chubb says—

1145

"The number of changes which may be effected on the keys of a three inch drawer lock is $1 \times 2 \times 3 \times 4 \times 5 \times 6 = 720$, the number of different combinations which may be made on the six steps of unequal lengths, without altering the length of either step. The height of the shortest step is however capable of being reduced 20 times; and each time of being reduced, the 720 combinations may be repeated; therefore $720 \times 20 = 14,400$ changes." By effecting changes of this character therefore, almost any number of combinations can be produced. The Bramah lock has been long celebrated, and most deservedly so. Notwithstanding the fact that this lock was picked by Mr. Hobbs after having the lock in his possession for sixteen days, it appears to us that it most fully justifies the boast made by Mr. Bramah in his "*Dissertation on the Construction of Locks*." "Being confident," he says, "that I have contrived a security which no instrument but its proper key can reach, and which may be so applied as not only to defy the art and ingenuity of the most skilful workman, but to render the utmost force ineffectual, and thereby to secure what is most valuable as well from dishonest servants as from the midnight ruffian, I think myself at liberty to declare (what nothing but the discovery of an infallible remedy would justify my disclosing) that all dependence on the inviolable security of locks, even of those which are constructed on the best principle of any in general use, is fallacious." He then proceeds to demonstrate the imperfections of ordinary locks and to describe his own.

"The body of a Bramah lock may be considered as formed of two concentric brass barrels, the outer one fixed, and the inner rotating within it. The inner barrel has a projecting stud, which, while the barrel is rotating, comes in contact with the bolt in such a way as to shoot or lock it; and thus the stud serves the same purpose as

the bit of an ordinary key, rendering the construction of a bit to the Bramah key unnecessary. If the barrel can be made to rotate to the right or left, the bolt can be locked or unlocked, and the problem is, therefore, how to insure the rotation of the barrel. The key, which has a pipe or hollow shaft, is inserted in the keyhole upon the pin, and is then turned round; but there must be a nice adjustment of the mechanism of the barrel before this turning round of the key and the barrel can be insured. The barrel has an external groove at right angles to the axis, penetrating to a certain depth; and it has also several internal longitudinal grooves from end to end. In these internal grooves thin pieces of steel are able to slide, in a direction parallel with the axis of the barrel. A thin plate of steel called the locking plate, is screwed in two portions to the outer barrel, concentric with the inner barrel; and at the same time occupying the external circular groove of the inner barrel; this plate has notches, fitted in number and size to receive the edges of the slides which work in the internal longitudinal grooves of the barrel. If this were all, the barrel could not revolve, because the slides are catching in the grooves of the locking plate; but each slide has also a groove, corresponding in depth to the extent of this entanglement; and if this groove be brought to the plane of the locking plate, the barrel can be turned, so far as respects the individual slide. All the slides must, however, be so adjusted, that their grooves shall come to the same plane; but, as the notch is cut at different points in the lengths of the several slides, the slides have to be pushed in to different distances in the barrel, in order that this juxtaposition of notches may be insured. This is effected by the key, which has notches or elevations at the end of the pipe equal in number to the slides, and made to fit the ends of the slides when the key is inserted; the key presses each slide, and pushes it so far as the depth of its elevations will permit; and all these depths are such that all the slides are pushed to the exact position where their notches all lie in the same plane; this is the plane of the locking plate, and the barrel can be then turned." (*Tomlinson on the Construction of Locks*.) In this work the details on construction are given with great clearness.

The American bank locks, especially that of Messrs Day and Newall, have excited much attention. Their English patent describes it thus:—

"The object of the present improvements is the constructing of locks in such manner that the interior arrangements, or the combination of the internal movable parts, may be changed at pleasure according to the form given to, or change made in, the key, without the necessity of arranging the movable parts of the lock by hand, or removing the lock or any part thereof from the door. In locks constructed on this plan the key may be altered at pleasure; and the act of locking, or throwing out the bolt of the lock, produces the particular arrangements of the internal parts, which correspond to that of the key for the time being. While the same is locked, this form is retained until the lock is unlocked or the bolt withdrawn, upon which the internal movable parts return to their original position, with reference to each other; but these parts cannot be made to assume or be brought back to their original position, except by a key of the precise form and dimensions as the key by which they were made to assume such arrangement in the act of locking. The key is changeable at pleasure, and the lock receives a special form in the act of locking according to the key employed, and retains that form until in the act of unlocking by the same key it resumes its original or unlocked state. The lock is again changeable at pleasure, simply by altering the arrangement of the movable bits of the key; and the key may be changed to any one of the forms within the number of permutations of which the parts are susceptible."—April 15, 1851.

Mr. Hobbs who has been carrying out the manufacture of American locks in this country has introduced an inexpensive lock, which he calls a *protektor lock*. The following description is borrowed from Mr. Charles Tomlinson's *Treatise on the Construction of Locks*:—

"When the American locks became known in England, Mr. Hobbs undertook the superintendence of their manufacture, and their introduction into the commercial world. Such a lock as that just described must necessarily be a complex piece of mechanism; it is intended for use in the doors of receptacles containing property of great value; and the aim has been to baffle all the methods at present known of picking locks, by a combination of mechanism necessarily elaborate. Such a lock must of necessity be costly; but in order to supply the demand for a small lock at moderate price, Mr. Hobbs has introduced what he calls a *protektor lock*. This is a modification of the ordinary six-tumbler lock. It bears an affinity to the lock of Messrs. Day and Newall, inasmuch as it is an attempt to introduce the same principle of security against picking, while avoiding the complexity of the changeable lock. The distinction which Mr. Hobbs has made between secure and insecure locks will be understood from the following proposition, viz. 'that whenever the parts of a lock which come in contact with the key are so affected by any pressure applied to

the bolt, or to that portion of the lock by which the bolt is withdrawn, as to indicate the points of resistance to the withdrawal of the bolt, such a lock can be picked. Fig. 1147 exhibits the internal mechanism of this new patent lock. It contains the usual contrivances of tumblers and springs, with a key cut into steps to suit the different heights to which the tumblers must be raised. The key is shown separately in fig. 1148. But there is a small additional piece of mechanism, in which the tumbler stump shown at *s* in figs. 1146 and 1147 is attached; which piece is intended to work under or behind the bolt of the lock. In fig. 1147, *b* is the bolt; *tt* is the front

or foremost of the range of six tumblers, each of which has the usual slot and notches. In other tumbler-locks the stump or stud which moves along these slots is riveted to the bolt, in such manner that, if any pressure be applied in an attempt to withdraw the bolt, the stump becomes pressed against the edges of the tumblers, and bites or binds against them. How far their biting facilitates the picking of a lock will be shown further on; but it will suffice here to say, that the movable action given to the stump in the Hobbs lock transfers the pressure to another quarter. The stump *s* is riveted to a peculiarly-shaped piece of metal *h p* (fig. 1146), the hole in the centre of which fits upon a centre or pin in a recess formed at the back of the bolt; the piece moves easily on its centre, but is prevented from so doing spontaneously by a small binding spring. The mode in which this small movable piece takes part in the action of the lock is as follows: when the proper key is applied in the usual way, the tumblers are all raised to the proper heights for allowing the stump to pass horizontally through the gating; but should there be an attempt made, either by a false key or by any other instrument, to withdraw the bolt before the tumblers are properly raised, the stump becomes an obstacle. Meeting with an obstruction to its passage, the stump turns the piece to which it is attached on its centre, and moves the arm of the piece *p* so that it shall come into contact with a stud riveted into the case of the lock; and in this position there is a firm resistance against the withdrawal of the bolt. The tumblers are at the same moment released from the pressure of the stump. There is a dog or lever *d*, which catches into the top of the bolt, and thereby serves as an additional security against its being forced back. At *k* is the drill-pin on which the pipe of the key works; and *e* is a metal piece on which the tumblers rest when the key is not operating upon them.

Another lock, patented by Mr. Hobbs in 1852, has for its object the absolute closing of the key-hole during the process of locking. The key does not work or turn on its own centre, but occupies a small cell or chamber in a revolving cylinder, which is turned by a fixed handle. The bit of the movable key is entirely separable from the shaft or stem, into which it is screwed, and may be detached by turning round a small milled headed thumb-screw. The key is placed in the key-hole in the usual way, but it cannot turn; its circular movement round the stem as an axis is prevented by the internal mechanism of the lock; it is left in the key-hole, and the stem is detached from it by unscrewing. By turning the handle, the key-bit, which is left in the chamber of the cylinder, is brought into contact with the works of the lock, so as to shoot and withdraw the bolt. This revolution may take place whether the bit of the movable key occupies its little cell in the plate or not; only with this difference—that if the bit be not in the lock, the plate revolves without acting upon any of the tumblers; but if the bit be in its place, it raises the tumblers

in the proper way for inserting or withdrawing the bolt. It will be understood that there is only one key-hole, namely, that through which the movable key is inserted; the other handle or fixed key working through a hole in the cover of the key only just large enough to receive it, and not being removable from the lock. As soon as the plate turns round so far as to enable the key to act upon the tumblers, the key-handle becomes entirely closed by the plate itself, so that the usual locking is effected at the very time when all locked in the interior through the key-hole is cut off. When the bolt has been shot, the plate comes round to its original position, it uncovers the key-hole, and enables the key to occupy the latter and into which it had been dropped; the stem is then to be screwed into the bolt, and the latter withdrawn. It is one consequence of this arrangement, that the key has to be screwed and unscrewed when used; but through this arrangement the key will become a sealed lock to one who has not the right key. Nothing can be moved, provided the bit and stem of the key be both left in; but by pulling in the bolt the former without the latter, the plate can rotate, the tumblers can be lifted, and the bolt can be shot.

LOCOMOTIVE ENGINES. The character of this work excludes any special notice of anything so entirely belonging to a work on Mechanical Engineering, as that of locomotive engines. Nevertheless, since so much has lately been said and written on the question of employing coal on our railways instead of coke, we are induced to introduce the following arrangement, which seems to combine without smoke. It is known as *Barry's plan*. The annexed drawing, Fig. 1147, is a section of a locomotive engine, used on the (Glasgow) Railway. The coal is thrown into the hopper A, which opens below the platform on which the engine stands. These pipes conduct the coal by their own gravity to the lower level of the bars, where they are thrust in the direction of the arrows C, D, by a kind of comb, or rotating pin, which in its rotation around the axis E, forces the coal to ascend the bars forward by the bars.

This then takes place the coal in its rude state (i.e. as it comes from the pit) coming from below, falls itself immediately in contact with the fire, which induces an escape of the gases, and with the pure air which permits their combustion to take place in the only condition in which it is possible, i.e. in small jets, which facilitate the complete oxygenation of all the parts.

The gases once produced and burnt, the rest of the operation scarcely needs explanation. The coal is converted into coke, and finishes its passage while burning under this form; and as the remainder of the solids, cinders and slag (or

clinkers), are not abandoned by the fire until after all that it contains of a combustible nature has disappeared, all the detritus (refuse) and dust, cinders, ashes, &c. are deposited on the surface (sommet) of the bars in the centre of the fire, where they would offer an obstruction similar to that found in ordinary fire-places, if the inventor had not taken care to make the bars oscillate from the centre by a small movement. Thus, when a drop of slag approaches the bars, it is displaced and thrown out (by the opening of the bars) in small particles. This necessary arrangement apparently possesses great advantages for a locomotive in saving the trouble of scraping and cleaning the bars.

So if, as in an ordinary fire, coke or anthracite, &c., be burnt, the combustion would be very complete. Air fresh from the ash-pit, in passing over the combustible, would be converted into carbonic acid, i.e. into a gas which is unfit for further combustion. But if in the place of coke or anthracite, &c. we use smoke-producing coal, i.e. com-

posed of two elements, one solid, the other gaseous, the result follows. The combustible gas disengaging themselves (in this case from the combustible) in a state of ignition, the air which will become vitiated in trying to burn the first bulk of the solid combustible, will be found unable to effect the combustion of the gases which escape above the fire, and smoke will make its appearance, i. e. the combustion will be incomplete and imperfect. This is what takes place with combustion of coal in ordinary fire-places.

There are also other causes which contribute to the imperfection of this result. These gases in disengaging themselves do not always acquire a temperature sufficiently high to produce flame, and the volume of combustible gas is almost always too considerable to allow of its being sufficiently penetrated with oxygen. These are some of the radical vices which M. Duméry has removed in thus placing the gases at once in the combustion heat suited for their combustion. This process is admirable, since, without any preparation, it allows of coal being burnt with as much facility as coke, and saves the great expense of converting coal into coke.

LOCUST TREE. A North American tree, the *Rubus parviflorus*. "It grows most abundantly in the southern States, but it is pretty generally diffused throughout the whole country. It sometimes exceeds four feet in diameter and seventy feet in height. The locust is one of the very few trees planted by the Americans."—*Stevenson's Civil Engineering of North America*. "This wood is much used for ships' tree-nails, and is employed for stakes and poles.

LODE (a mining term). A mineral lode, or a mineral vein, is the name given to a fissure in the crust of the earth which has been filled in with metalliferous matter. The miner gives the same name *lode* to a fissure filled with quartz, carbonate of lime, &c., but then he says the lode is not "mineralised," confining the word mineral to metalliferous matter.

The term vein has frequently led to the idea that it expresses the condition of something analogous to the blood vessels of the animal body, to which a lode has not in the remotest degree, any resemblance. During some primary convulsions, the crust of the earth has been cracked, these fissures having, of course, some special relation to the direction of the force which produced them. These cracks have during ages of submergence been filled in, according to some law of polarity with mineral matter, the character of the lode having generally some special relation to its direction. See *Mining*, &c.

LOGWOOD (*Bons de Campêche*, *Bois bleu*, Fr.; *Blauholtz*, Germ.) is the wood of the *Hæmatarylon Campachianum*, a native tree of Central America, grown in Jamaica since 1715. It was first introduced into England in the reign of Elizabeth, but as it afforded to the unskilful dyers of her time a fugitive colour, it was not only prohibited from being used, under severe penalties, but was ordered to be burned whenever found, by a law passed in the 23rd year of her reign. The same prejudices existed, and the same law was enacted against indigo. At length, after a century of absurd prohibition, these two most valuable dyestuff matters, by which all our luns, and the greater part of our woollen cloths, are dyed, were allowed to be used. The logwood trees grow from 40 to 50 feet high, the stems are cut into logs of about 3 feet long, the bark and white sap (albumen) of which are clipped off, the heart or red part only being sent to England. Chevreul gave the constituents of logwood as *volatile oil*, *hematin*, *resinous matter*, *tannin*, *glutinous matter*, *acetic acid*, *sundry salts of lime*, with *alumina*, *silica*, *manganese*, and *iron*. The decoction of logwood is of a deep dull red, which is rendered paler and of a brighter colour by acids. Alkalies give it a purplish or violet colour. Acetate of lead causes a blue, alum a violet precipitate; the salts of iron make it a dark violet blue, gelatine forming a reddish precipitate with it.

Old wood, with black bark and with the tile of the white albumen, is preferred. Logwood is denser than water, specific gravity, 1.057, very hard, of a fine compact grain, and almost indestructible by the atmospheric elements; it has a sweet and stringent taste, and a peculiar but inoffensive smell, and will take a fine polish.

When clipped logwood for some time exposed to the air, it loses a portion of its dyeing power. Its decoction absorbs the oxygen of the atmosphere, and then acquires the property of precipitating with gelatine, which it had not before. The dry extract of logwood, made from an old decoction, affords only a fugitive colour.

For its applications in dyeing, see **BLACK DYE**; **CALICO PRINTING**; **DYEING**; **HAT DYEING**, &c.

The imports of logwood were in

	Total	Value

1837 - - -	39,563 - -	236,080

LOOKING GLASS. See **MIRROR**.

LOOM (*Metier a tisser*, Fr.; *Weberstuhl*, Germ.) is the ancient and well-known machine for weaving cloth by the decussation of a series of parallel threads, which run lengthwise, called the warp or chain, with other threads thrown transversely with the shuttle, called the woof or weft. See **JACQUARD LOOM** and **WEAVING**.

LUBRICANTS. Oleaginous or fatty bodies employed for the purpose of reducing the friction between two parts of a machine or carriage.

LUBRICATION. The lubrication of the wheel and axle of railway carriages is effected by a kind of soap, a combination of cocoa-nut oil or palm-oil, or ordinary tallow, with soda being the "grease" with which the boxes are filled. The heat produced by the friction melts the grease, and it flows out upon the parts in motion through an opening in the bottom of the box. Heavy machinery, such as pumping engines, require tenacious bodies as their lubricants, while the finer parts must be carefully oiled with oils as free as possible from any of the fatty acids. Spinning machinery for example, must be lubricated with the finest oils, or, as is found to be still better, with those peculiar hydro-carbon compounds, as paraffine, glycerine, and the like. The following is a simple and efficacious plan of lubricating the joints and bearings of machinery by capillary attraction, the invention of Edward Woolsey, Esq. :—

Fig. 1150 represents a tin cup, which has a small tin tube *A*, which passes through the bottom, as shown by the dotted lines. It may have a tin cover to keep out the dust.

Fig. 1151 is a plan of the same.

Fig. 1152 is a section of the same. Oil is poured into the cup, the one end of a worsted or cotton thread is dipped into the oil, and the other end passed through the tube.

The capillary attraction causes the oil to ascend and pass over the orifice of the tube, whence it gradually descends, and drops slower or quicker according to the length of the thread or its thickness, until every particle of oil is drawn over by this capillary siphon. The tube is intended to be put into the bearings of shafts, &c., and is made of any size that may be wished. If oil, or other liquids, is desired to be dropped upon a grindstone or other surface,

this cup can have a handle to it, or be hung from the ceiling.

Fig. 1153. It is frequently required to stop the capillary action when the machinery is not going; and this has been effected by means of a tightening screw, which passes through a screw hole in the cover of the cup, and presses against the internal orifice of the tube, preventing the oil from passing.

Fig. 1154. As when these screw cups are used upon beams of engines and moving bearings, the screw is apt to be tightened by the motion; and also, as the action of the screw is uncertain, from the workman neglecting to screw it down sufficiently, it answers best to take out the capillary thread when the lubrication is not required; and to effect this easily, a tin top is fixed to the cup, with a round pipe soldered to it; this pipe has a slit in it, like a pencil case, and allows a bolt *B* to slide easily. In fig. 1155 the bolt is down; in fig. 1156 the bolt, which is a piece of brass wire, is drawn up, and thus the flowing of the oil is checked. In fig. 1156 it will be observed, that the bolt is kept in its place by its head *C*, resting in a lateral slit in the pipe, and it cannot be drawn out on account of the pin *D*. One end of the thread is fastened to the eye hole at the bottom of the bolt, and the other end is tied to a small wire which crosses the lower orifice of the tube at *E*, and which is shown in plan fig. 1157.

The saving by this plan, instead of pouring oil into the bearings, is 2 gallons out of 3, while the bearings are better oiled.

The saving in labour is considerable where there are many joints to keep oiled three or four times a day; and the workman does not, with this apparatus, run the risk of being caught by the machinery. To tie on the cotton or worsted thread, pass a long thread through the eye-hole of the bolt, and then draw the two ends through the tube by a fine wire with a hook to it, one end on one side of the cross wire in, and the other end on the other side. Then put the cover on, and the bolt in the position shown in fig. 1156; when by drawing the two ends of the thread, and tying them across the wire D, you have the exact length required. When you wish to see the quantity of oil remaining in the lubricator, the bolt must be dropped as in fig. 1155, and you can then lift the cover a little way off, without breaking the thread, and replenish with oil. The figures in the woodcuts are one third of the full size.

LUCIFER MATCHES. The importance of this manufacture has been shown by Mr. Tomlinson in a communication made by that gentleman to the Journal of the Society of Arts.

"It has been estimated," he says, "that the English and French manufacturers of phosphorus are now producing at the rate of 300,000 lbs. of common phosphorus per annum, nearly the whole of which is consumed in making lucifer matches. In compounding the emulsion for tipping the matches, the German manufacturers make three pounds of phosphorus suffice for five or six millions of matches. If we suppose only one half of the French and English annual product of phosphorus to be employed in making matches, this will give us 250,000,000,000 of matches as the annual product consequent on the consumption of one half of the French and English phosphorus. We need not suppose this to be an exaggerated statement, when we consider the daily product of some of our match manufactories. I lately had occasion to describe the processes of a London factory, which produces 2,500,000 matches daily. For this purpose, 14 3-inch planks are cut up; each plank produces 30 blocks; each block, of the dimensions of 11 inches long, 4½ inches wide, and 3 inches thick, produces 100 slices, each slice 31 splints, each splint 2 matches. thus we have— $14 \times 30 \times 100 \times 31 \times 2 = 2,604,000$ matches as the day's work of a single factory in London. At Messrs. Dixon's factory near Manchester, from 6,000,000 to 9,000,000 of matches are produced daily."—Tomlinson.

For the rapid manufacture of the wooden splints for lucifer matches, a patent was obtained by Mr. Reuben Partridge, in March, 1842. He employs a perforated metallic plate, having a steel face, strengthened by a bell metal back; see figs. 1158, 1159. The size of the perforations must depend on that of the desired splints, but they

must be as close together as possible, that there may be a very small blank space between them, otherwise the plate would afford too great resistance to the passage of the wood. By this construction, the whole area of the block of wood may be compressed laterally into the countersunk openings, and forced through the holes, which are slightly countersunk to favour the entrance and separation of the wooden fibres.

Fig. 1128 represents the face of one of these plates; and fig. 1129 is a rectangular section through the plate. A convenient size of plate is three inches broad, six inches long, and one thick. The mode of pressing is by fixing the back of the plate against a firm resisting block or bearing, having an aperture equal to the area of the perforations in the plate, and then placing the end of the piece or pieces of wood in the direction of the grain against the face of the plate within the area of the perforated portion. A plunger or lever or other suitable mechanical agent being then applied to the back or reverse end of the piece of wood, it may be forced through the perforations in the plate, being first split as it advances by the cutting edges of the holes, and afterwards compressed and driven through the perforations in the plate, coming out on the opposite side or back of the plate in the form of a multitude of distinct splints, agreeably to the shapes and dimensions of the perforations.—*Newton's Journal*, O. S. vol. xxii. 263.

Manufacture of Lucifers.—The first stage in the manufacture of lucifers is the cutting the wood, which is done, according to the extent of the manufactory, either by hand or by machinery. This, as well as the subsequent process of counting and placing the matches in frames, is in itself necessarily free from any inconvenience or evil consequences; nor does it appear that the third stage, which consists of melting the sulphur and dipping the heads of the matches in it, produces any inconvenience. The fourth, fifth, sixth, and seventh stages comprise the grinding, mulling, and mixing of the explosive compound; the process of dipping the matches in it, the counting and boxing. The dipping, counting, and packing, appear to be, according to Mr. Geist, the only departments in which the workpeople are in any way affected with peculiar complaints; we would even limit the appearance of the jaw disease to those engaged in dipping; at least all that we have examined on the subject were unanimous as to the fact that dippers only were attacked. There is a certain degree of secrecy observed relative to the proportions of the composition; and the mixture of the materials is generally formed by the proprietor of the manufactory, or by a confidential workman. Chloride of potash is considered an essential ingredient in England; but in the manufactory at Nürnberg it has not been employed for a number of years, as its explosive properties much endangered the safety of the buildings and the limbs of the workmen.

The composition used in Nürnberg consists of one-third of phosphorus, of gum arabic (which is eschewed by English manufacturers on account of its hygroscopic property), of water, and of a coloring matter, for which either minium or Prussian blue is employed. If ignition be required without a flame, the quantity of phosphorus is diminished, or nitrate of lead is added. The mixing is conducted in a water-bath; and during this process, and as long as the phosphorus is being ground or "mullered," the composition is spread upon a board covered with cloth or paper, and the workman dips the two ends of the matches alternately that are fixed in the frame; and as this is done with great rapidity, the disengagement of fumes is very considerable, and is more liable to be injurious, as they are evolved in a very concentrated form close to the face of the workman. This department is generally left to a single workman; and the average number that he can dip in an hour, supposing each frame to hold 3,000 matches, would be 1,000,000.

As the matches have been dipped, they require to be dried. This is generally done in the room in which the former process is carried on; and as a temperature of from 50° to 90° Fahr. is necessary, the greatest quantity of fumes is evolved at this stage. When the matches are dried, the frames are removed from the drying room, and the lucifers are now ready to be counted out into boxes. As this is done with great rapidity, they frequently take fire, and, although instantly extinguished in the sawdust or the water which is at hand, the occurrence gives rise to an additional and frequent evolution of fumes.

According to Dr. R. Boettger, in *Annalen der Chemie und Pharmacie*, vol. xlvii. p. 334, the best composition for lucifer matches is

Phosphorus - - -	4 parts	Red ochre, or red lead - -	5 parts
Nitre - - -	10 "	Smalt - - -	2 "
Fine glass - - -	6 "		

Convert the glass with a little water by a gentle heat into a smooth jelly; put it into a slightly warm porcelain mortar to liquefy; rub the phosphorus down through this gelatine at a temperature of about 140° or 150° Fahr.; add the nitre, then the red powder, and lastly the smalt, till the whole forms a uniform paste. To make writing-paper matches, which burn with a bright flame and diffuse an agreeable odour, moisten each side of the paper with tincture of benzoin, dry it, cut it into slips, and smear one of their ends with a little of the above paste by means of a hair pencil. On rubbing the end after it is dry against a rough surface the paper will take fire, without the intervention of sulphur.

To form lucifer wood matches, that act without sulphur, melt in a flat-bottomed

tin pan as much white wax as will stand one-tenth of an inch deep; take a bundle of wooden matches free from resin, rub their ends against a red hot iron plate till the wood be slightly charred; dip them now in the melted wax for a moment, shake them well on taking them out, and finally dip them separately in the above viscous paste. When dry, they will kindle readily by friction.

A "*Safety Lucifer Match*," as it is called, has been manufactured in Sweden. Its patent was obtained in that country by Messrs. Bryant and May, for this match. Its peculiarity consists in the division of the combustible ingredients of the lucifer between the match and the friction paper. In the ordinary lucifer, the phosphorus, sulphur, and chlorate of potash or nitre, are all together on the match, which ignites when rubbed against any rough substance. In the Swedish matches these materials are so divided that the phosphorus is placed on the sand-paper, whilst the sulphur and a minimum amount of chlorate or nitrate of potash is placed on the match. In virtue of this arrangement it is only when the phosphorised sand-paper and the sulphurised match come in contact with each other that the ignition occurs. Neither match nor sand-paper, singly, takes fire by moderate friction against a rough surface.

The composition of lucifer matches varies greatly, as it regards the proportions of the materials employed. In principle they are, however, as we have described them above; everything depending on the ignition of the phosphorus, and the perfection of a lucifer match is in tipping the match with a composition which will ignite quietly upon attrition against any rough surface, but which is not liable to ignite by such pressure as it may be subjected to under the ordinary condition of keeping in closed boxes.

The preparation of lucifer matches has been attended with much human suffering. Every person engaged in a factory of this kind is more or less exposed to the fumes of phosphorus, and this exposure produces a disease which has been thus described by Mr. Harrison, in the *Quarterly Journal of Medical Science*.—"This disease," he says, "is of so insidious a nature that it is at first supposed to be common toothache, and a most serious disease of the jaw is produced before the patient is fully aware of his condition. The disease gradually creeps on, until the sufferer becomes a miserable and loathsome object, spending the best period of his life in the wards of a public hospital. Many patients have died of the disease; many, unable to open their jaws, have lingered with carious and necrosed bones; others have suffered dreadful mutilations from surgical operations, considering themselves happy to escape with the loss of the greater portion of the lower jaw."

By the introduction of an amorphous phosphorus discovered by M. Schrotter, which is in nearly all respects unlike the ordinary phosphorus, but which answers exceedingly well for the manufacture of lucifer matches, this disease is prevented, the manufacture is rendered more healthy, and the boxes of matches themselves less dangerous. See PHOSPHORUS. In 1857 our imports and exports were—

LUMACHELLE, or *Fire Marble*. This is a dark brown shelly marble, having brilliant fire or *chatoyant* reflections from within.—See MARBLE.

LUNAR CALSTIC. A name for nitrate of silver, when fused and run into cylindrical moulds.

LUPININE, is a substance of a gummy appearance, so named by M. Cuscola, because it was obtained from Lupines.—C. G. W.

LUPULINE, from *Humulus Lupulus*; is the peculiar bitter aromatic principle of the hop. See BEER.

LUSTRING, sometimes spelled also *lustre*, used *Lustrestring*; a peculiar shining silk.

LUTE (from *lutum*, clay; *Lut*, Fr.; *Kutte*, *Bewlut*, Germ.) is a paste or loamy matter employed to close the joints of chemical apparatus, or to coat their surfaces, and protect them from the direct action of flame. Lutes differ according to the nature of the vapours which they are destined to confine, and the degree of heat which they are to be exposed to.

1. *Lute of accidental*, made into a soft plastic dough with water, and immediately applied pretty thick to junctions of glass, or stone-ware, makes them perfectly tight, hardens speedily, resists acid and ammoniacal vapours, as also a moderate degree of heat. It becomes stronger when the meal is kneaded with milk, lime-water, or solution of glue, and is the best lute for fluo-silicic acid.

2. *Lute of thick gum-water*, kneaded with clay, and iron filings, serves well for permanent junctions, as it becomes extremely solid.

3. By softening in water a piece of thick brown-paper, kneading it, first with yeflower paste, and then with some paper's clay, till it acquire the proper consistence, a lute is formed which does not readily crack or scale off.

4. Lute, consisting of a strong solution of glue kneaded into a dough with new slaked lime, is a powerful cement, and with the addition of white of egg forms the *lut d'œuf*; — a composition adapted to mend broken vessels of porcelain and stone-ware.

5. Skim-milk cheese, boiled for some time in water, and then triturated into paste with fresh-slaked lime, forms also a good lute.

6. Calcined gypsum, diffused through milk, solution of glue, or starch, is a valuable lute in many cases.

7. A lute made with linseed, melted caoutchouc, and pipe-clay, incorporated into a smooth dough, may be kept long soft when covered in a cellar, and serves admirably to confine acid vapours. As it does not harden, it may therefore be applied and taken off as often as we please.

8. Caoutchouc itself, after being melted in a spoon, may be advantageously used for securing joints against chlorine and acid vapours, in emergencies when nothing else would be effectual, or we may use 1 part of caoutchouc dissolved in two parts of hot linseed-oil, and worked up with pipe-clay (3 parts) into a plastic mass. It bears the heat at which sulphuric acid boils.

9. The best lute for joining crucibles inverted into each other, is a dough made with a mixture of fresh fire-clay, and ground fire-bricks, worked with water. That cement, if made with solution of borax, answers still better, upon some occasions, as it becomes a compact vitreous mass in the fire.

LUTEOLINE, is the colouring principle of the weld (*Remeda luteola*), a slender plant growing to the height of about three feet, and cultivated for the use of dyers. When ripe it is cut and dried.

Chevreul was the first to separate the *luteoline*; it is extracted from the weld by boiling water, and when this solution is concentrated and allowed to cool, the luteoloe separates; it is then collected, dried, and submitted to sublimation, when it is condensed in yellow needles.

It is valued for its durability, and is used as a yellow dye, on cottons principally, and also on silks, but is little used at present. It was formerly used by paper-hanging manufacturers, to form a yellow pigment, but has been entirely superseded for that purpose, by *quercitron bark* and *Persian berries*. It unites with acids and alkalies, the former making the colour paler, and the latter heightening the colour. The compound which it forms with potash is of a golden colour, becoming greenish when exposed to the air, by absorption of oxygen, and at length becomes red.

It forms yellow compounds with alum, protochloride of tin, and acetate of lead; with the salts of iron it produces a blackish grey precipitate, and with sulphate of copper a greenish brown precipitate.

It is readily soluble in alcohol and ether, but sparingly so in water — H. K. B.

LUTIDINE, C₁₂H₁₁N. A volatile nitryle base, discovered by Anderson in bone oil. It has also been found in shale naphtha, coal naphtha, and in crude chinoline. — C. G. W.

LYCOPodium CLAVATUM. The seeds of the lycopodium ripen in September. They are employed, on account of their great combustibility, in theatres, to imitate the sudden flash of lightning, by throwing a quantity of them from a powder puff, or bellows, across the flame of a candle.

LYDIAN STONE, *Tourmaline*, or *Bastanite*. A flinty variety of jasper, used on account of its hardness, fine texture, and velvet black colour, for trying the purity of the precious metals. The amount of alloy is indicated by the colour left on the stone after the metal has been rubbed across it.

LYNX. — An animal producing a favourite fur of a greyish white, with dark spots.

OF

ARTS, MANUFACTURES, AND MINES.

D

DAGUERRETYPE. A photographic process discovered by M. Daguerre, a celebrated French dioramic painter, and published in July, 1839; the French Government having secured a pension for life of 6000 francs on M. Daguerre, and of 4000 francs on M. Isidore Niepce, the son of M. Nicéphore Niepce, who had for some time been associated with Daguerre in carrying forward the experiments which led to M. Daguerre's discovery.

It is rendered clear from some of Niepce's letters, that he had abandoned all hope of succeeding with iodine, upon which the sensibility of the Daguerreotype plate entirely depends. In a letter to Daguerre, Niepce says, "I repeat it, &c. I do not see that we can hope to derive any advantage from this process—the use of iodine—in it then from any other method which depends on the use of metallic oxides," and in another he writes, "A decoction of thiaspi (shepherd's purse), fumes of phosphorus, and particularly of sulphur, as acting on silver in the same way as iodine, and capable of producing the same effect by oxidising the metal, for from this cause proceeded all these instances of extreme sensibility to light." Niepce died in July, 1833. Daguerre proceeded with his experiments for nearly six years, before he succeeded in producing the desired result. The Daguerreotype process depends on the production of a very delicate chemical compound of iodine and silver, on the surface of a carefully prepared silver-plate. This compound is immediately formed by the reaction proceeding from any external object illuminated by the sun. The reaction is developed by the action of mercurial vapour, and lastly rendered permanent as far as the action of light is concerned, by dissolving off the iodine of silver, by hyposulphite of soda. According to the first published description by Daguerre, the process is divided into five operations. The first consists in polishing and cleaning the silver surface, by friction with cotton fleece imbued with olive oil, upon the plate previously dusted over with very finely-ground dry pumice-stone out of a wooden box. The hand of the operator should be moved round in circles of various diameters. The plate should be laid upon a sheet of paper suitably supported. The paper must be pinned to an impalpable powder upon a porphyry slab with water, and then dried. The surface is next to be rubbed with a dozel of cotton, slightly moistened with distilled water, and with sixteen parts of water, by applying the dozel to the surface of the plate, and inverting it for a moment. Two or three such dozels should be used in succession. The plate is lastly to be sprinkled with pumice powder or Venetian trowel, and rubbed clean with cotton.

The plate is then placed in a wire frame, with the silver surface uppermost, over a spirit lamp, meanwhile moving it so as to act equally on every part of the plate. In about five minutes a whitish coating will be formed, and the operation is completed. The plate must now be laid upon a flat metal or marble slab to cool it quickly. The white surface is to be brightened by rubbing it with cotton and pumice powder. It must be once more rubbed with the cotton and water, and afterwards with the frame with cotton and pumice, avoiding to touch the plate with the fingers, or with the part of the cotton held in the hand, or to breathe upon the plate. Some operators wash the

be produced. After cleaning with cotton alone, the plate is ready for the next operation.

The second stage is that of iodising the plate; a box is prepared, having iodine strewed over its bottom, and the silver plate, face downwards, is placed a few inches above the iodine, and the lid of the box being closed, all is left at rest for a short time. The plate must be left in this position till the surface of the silver acquires a fine golden hue, caused by the vapours of the iodine rising and condensing upon it; but it should not be allowed to assume a violet tint. The room should be darkened, and no heat should be employed. When the box is in constant use it gets impregnated with iodine, and acts more uniformly and rapidly; but in general states of the atmospheric temperature this operation will be effected in about twenty minutes. If the purple colour be produced, the plate must be repolished, and the whole process repeated.

The plate with its golden hue is to be introduced with its frame to the camera obscura. During this transfer the light must not be suffered to strike upon the surface of the plate; no which account, the camera obscura may be lighted briefly with a small wax taper.

The plate is now submitted to the third operation, that of the camera obscura, and with the least possible delay. The action of this machine is obviously quicker the brighter the light which acts upon it; and more correct, according as the focus is previously accurately adjusted to the place of the plate, by moving backwards and forwards a roughened pane of glass, till the focal point be found; and the plate is to be inserted precisely there. This apparatus exactly replaces the ground glass. While the prepared plate is being fastened, the camera must be closed. The plate is now in a proper position to receive and retain the impression of the image of the objects presented the moment that the camera is opened. Experience alone can teach the proper length of time for submitting the plate to the concentrated rays of light; because that time varies with the climate, the seasons, and the time of day. More time should not be allowed to pass than what is necessary for fixing a distinct impression, because the parts meant to be clear would be apt to become clouded. The impression of the image of nature is now actually made upon the plate; but it is as yet invisible; and it is only after a lapse of several minutes, during which it is exposed to mercurial vapour, that faint tracings of the objects begin to be seen.

The fourth is the operation with quicksilver, which must follow as soon as possible the completion of the third. Here a phial of quicksilver, a spirit lamp, and a glass funnel with a long neck, are required. The funnel is used for pouring the mercury into a cup, placed in the bottom of an apparatus which will allow of the application of heat. No daylight must be admitted to the mercury box, a small taper only being used to examine, from time to time, the effects. The plate with the dormant image is placed some distance above the mercury, which vaporising, evokes in a truly magical manner, the delicate lines which the solar pencil has traced.

After each operation, the interior of the apparatus, and the black board or frame should be carefully wiped, in order to remove every particle of mercury. The picture may now be inspected in a feeble light, to see how far the process has succeeded. The plate, freed from the metallic loads, is to be placed in a box, provided with a cover and grooves, to exclude the light, till it is made to undergo the last operation. For the fifth and last operation the following articles are now required:—strong brine, or a weak solution of hyposulphite of soda; two troughs of tin plate, and a jug of distilled water. The object of this process is to fix the photographic picture. One of the troughs is to be filled with brine to the depth of an inch, and the other with pure water, both liquids being heated somewhat under the boiling point. The solution of hyposulphite of soda is preferable, and does not need to be warm. The plate is to be first immersed in the pure water for a moment, and transferred immediately to the saline solution, and moved to and fro in it to equalise the action of the liquor. Whenever the yellow tint of the iodine is removed, the plate is to be lifted out by the edges, and dipped straightway in the water-trough. The plate, when lifted out of the water-trough, is to be placed immediately on an inclined plane; and without allowing it time to dry, is to be floated over with the hot distilled water from the top, so as to carry off all the saline matter. As the quicksilver which traces the images will not bear touching, the silvered plate should be secured by a cover of glass, made tight at the edges by pasting paper round them.

The Daguerreotype process as thus published, although even then an exceedingly beautiful process, was not sufficiently sensitive to enable the operator to obtain portraits from the life. A period of twenty minutes was required even with the most favourable light to produce the desired effect. Numerous modifications were speedily introduced, and many of them were patented.

The progressive advance of this branch of the photographic art, though of great

interest, cannot be dwelt on in this place. Those who are interested in the inquiry, will find the information fully detailed in Hunt's *Manual of Photography*, 5th Edition, 1857. It will be sufficient in this work to detail the more important improvements which have become generally adopted. The first advance of real importance was made by Mr. Towson, of Devonport, who has since that time distinguished himself by the introduction of his system of Great Circle Sailing. Mr. Towson suggested the use of enlarged lenses, and by acting with such, Dr. Draper, of New York, was the first to procure a portrait from the life. Still this was a tedious process, but in 1840, Mr. Goddard proposed the use of bromide of iodine, by which infinitely increased sensibility was obtained. From that time the Daguerreotype was generally employed for portraiture, until the facilities of the collodion process drove it from the field.

The improved manipulation now resolves itself into

Carefully polishing the silver plate after some of the methods previously described, and the application finally of the highest polish by the use of a buffer, the best form being that employed by M. Claudet.

In a box on a roller, to which there is a handle, *fig. 638*, is placed a long piece of

638

drab-coloured velvet, which can be drawn out and extended by means of a second roller upon a perfectly flat table. The first foot or two, for example, is drawn out; the plate which has already received its preliminary polishing is placed face downwards, and being pressed close with the fingers, a rapid circular motion is given to it, and in a few minutes it receives its highest lustre. As the velvet becomes blackened by use, it is rolled off, the portion remaining in the box being always perfectly clean and ready for use.

The iodining process follows: and for this purpose a box similar to that represented will be found to be very convenient, (*fig. 639*).

This iodining apparatus consists of a square box with a closely fitting cover *a*, false sides are placed at an angle with this box, a cup *b* at the bottom contains the iodine, which is covered with a thin gauze screen *s s*. *c* is a cover which confines the iodine when it is not required for the plate; this dividing the box into two parts, *u u*, and *x x*, the former being always full of iodine vapour. When it is desired to iodine a plate, the cover *c* is removed, the silver plate is placed at *x*, and the cover *a* closed.

The plate is thus placed in the iodine box until it acquires a fine straw yellow colour. In another box is placed either bromine or some one of the many accelerating fluids. If bromine, or any bromide is employed, the plate should remain until it becomes of a rose colour. As a general rule, if the yellow colour produced by iodine be pale, the red should be pale also; if deep, the red must incline to violet.

The proper time for exposing a plate to any of those chemical substances which are destined to produce the sensitive film, must vary with the temperature, and it can only be determined by experience. The sensitive plate is now removed to the camera obscura, for a description of which see *PHOTOGRAPHY*. It is scarcely necessary to say, that the plate must be preserved in perfect darkness until exposed to the image in the camera. A few seconds when the plate is properly prepared will be found amply sufficient to produce the best effect.

The impression must be developed in the mercury box (*fig. 640*) in the manner described by Daguerre. This mercurial box consists of a box mounted on legs, having a close fitting cover *a*, and an iron bottom in which is placed the mercury *c*.

639

and a small thermometer *r* to indicate the proper temperature. *n* is a piece of glass

640

let into the side of the box through which the Daguerreotype plate is fixed in the frame it can be seen. *n* is a spirit-lamp, and *t* the platform on which it stands. The subject is eventually fixed by the use of hyposulphite of soda, which removes the bromo-iodide of silver, and leaves a picture produced by the contrast between a combination of the silver and mercury, and the surface of the unchanged polished silver.

The application of chloride of gold to the finished picture was introduced by M. Fizeau.

Chloride of gold applied to the picture has the effect of fixing and enlivening the tints. A small grate being fixed by a clamp to the edge of a table, the plate is laid upon it with the image uppermost, and overspread evenly with solution of chloride of gold, by means of a fine broad camel hair brush, without letting any drop over the edge. A spirit lamp is now brought under the plate, and moved in and fro till a number of small steam bubbles appear upon the image. The spirit lamp must be immediately withdrawn. The remainder of the chloride solution must be poured back into the phial, to be used on another occasion. It is lastly to be washed and examined. This operation has been repeated three or four times with the happiest effect of giving fixity and force to the picture. It may then

be wiped with cotton without injury. The process of colouring these pictures is a purely artificial one, while, while it destroys the beauty of the photograph, does not in any way improve it as a picture.

Daguerreotype Engraving.—Several processes for etching the Daguerreotype plate were introduced with more or less success. Professor Grove produced a few good engravings by the action of voltaic electricity. Berard and Bequerel were also enabled to produce some promising results by a similar process. The following process by M. Claudet was carried out to some extent with every prospect of success.

The new art, patented by M. A. F. J. Claudet on the 21st November, 1843, was established on the following facts. A mixed acid, consisting of water, nitric acid, nitrate of potash, and common salt in certain proportions, being poured upon a Daguerreotype picture, attacks the pure silver, forming a chloride of that metal, but does not affect the white parts, which are produced by the mercury of the picture. This action does not last long. Water of ammonia, containing a little chloride of silver in solution, dissolves the rest of that chloride, which is then washed away, leaving the naked metal to be again attacked, especially with the aid of heat. The metallic surface should have been perfectly purified by means of alcohol and caustic potash. For the rest of the ingenious but complex details, see *Newton's Journal*, C. S. vol. xiv. p. 112. — See ACTINIAN, COLLODION, PHOTOGRAPHY.

DAMULINE, the same as **ISULINE**. The fecula obtained from elecampane, analogous in many respects to starch. It has not been employed in the arts.

DAMAR GUM, or **DAMARA RESIN**. A pale yellow resin, somewhat resembling copal, and used like it in the manufacture of varnishes. Dammar resin is said to be derived from the *Pinus dammara alba* of India. A Dammar resin is also imported from New Zealand, which is the product of the *Dammar Australis*. Under the name of Cowdie resin it is said to be used extensively as a varnish in America. "Dammar is easily dissolved in oil of turpentine, and when carefully selected is almost colourless; it makes a softer varnish than mastic; the two combined, however, form an almost colourless varnish, moderately hard and flexible, and well suited for maps and similar purposes." — *Holtzappel*.

DAMASCUS BLADES, are swords or scymitars, presenting upon their surface a variegated appearance of watering, as white, silvery, or black veins, in fine lines, or fillets; fibrous, crossed, interlaced, or parallel, &c. They are brought from the East, being fabricated chiefly at Damascus, whence their name. Their excellent quality has become proverbial; for which reason these blades are much sought after by military men, and are high priced. The ancient processes have never been satisfactorily described; but of late years methods have been devised in Europe to imitate the fabric very well.

Clouet and Hachette pointed out the three following processes for producing Damascus blades: 1, that of *parallel fillets*; 2, that by *twisting*; 3, the *mosaic*. The first, which is still pursued by some French cutlars, consists in sawing out with a graving tool the faces of a piece of stuff composed of thin plates of different kinds of steel. These hollows are by a subsequent operation filled up, and brought to a level with the external faces, upon which they subsequently form truss like figures. 2. The method of *twisting*, which is more generally employed at present, consists in forming a bundle of rods or slips of steel, which are welded together into a well-wrought bar, twisted several times round its axis. It is repeatedly forged, and twisted alternately, after which it is slit in the line of its axis, and the two halves are welded with their outside in contact; by which means their faces will exhibit very various configurations. 3. The *mosaic* method consists in preparing a bar, as by the *twisting* plan, and cutting this bar into short pieces of nearly equal length, with which a saggot is formed and welded together; taking care to preserve the sections of each piece at the surface of the blade. In this way, all the variety of the design is displayed, corresponding to each fragment of the cut bar.

The blades of Clouet, independently of their excellent quality, their flexibility, and extreme elasticity, have this advantage over the oriental blades, that they exhibit in the very substance of the metal, designs, letters, inscriptions, and, generally speaking, all kinds of figures which had been delineated beforehand.

Notwithstanding these successful results of Clouet, it was pretty clear that the watered designs of the true Damascus scymtars were essentially different. M. Briant has attempted a solution of this problem. He supposes that the substance of the oriental blades is a cast steel more highly charged with carbon than our European steel, and in which, by means of a cooling suitably conducted, a crystallisation takes place of two distinct combinations of carbon and iron. This separation is, he thinks, the essential condition; for if the melted steel be suddenly cooled in a small crucible or ingot, there is no damascene appearance.

If an excess of carbon be mixed with iron, the whole of the metal will be converted into steel; and the residuary carbon will combine in a new proportion with a portion of the steel so formed. There will be two distinct compounds; namely, pure steel, and carburated steel or cast-iron. These at first being imperfectly mixed, will tend to separate if while still fluid they be left in a state of repose, and form a crystallisation in which the particles of the two compounds will place themselves in the crucible in an order determined by their affinity and density combined. If a blade forged out of steel so prepared be immersed in acidulous water, it will display a very distinct Damascus appearance; the portions of pure steel becoming black, and those of carburated steel remaining white, because the acids with difficulty disengage its carbon. The slower such a compound is cooled, the larger the Damascus veins will be. Tavernier relates that the steel crucible ingots, like those of wood, for making the true oriental Damascus, come from Golkonda, that they are the size of a halfpenny reel, and when cut in two, form two swords.

Steel combined with manganese displays the Damascus appearance very strongly.

A mixture of 100 parts of soft iron, and 3 of lamp black, heats as readily as ordinary steel. Several of the best blades which M. Briant presented to the Société d'Encouragement are the product of this combination. This is an easy way of making cast-steel without previous cementation of the iron. 100 parts of filings of very grey cast-iron, and 100 parts of like filings previously oxidised, produced, by their fusion together, a beautiful damascene steel, fit for forging into white arms, sabres, swords, &c. This compound is remarkable for its elasticity, an essential quality, not possessed by the old Indian steel. The greater the proportion of the oxidised cast-iron the tougher is the steel. Care should be taken to stir the materials during their fusion, before it is allowed to cool; otherwise they will not afford a homogeneous damasc. If the steel contains much carbon it is difficult to forge, and cannot be drawn out except within a narrow range of temperature. When heated to a red-white it crumbles under the hammer; as a cherry-red it becomes hard and brittle, and as it progressively cools it becomes still more unmanageable. It resembles completely Indian steel, which European blacksmiths cannot forge, because they are ignorant of the suitable temperature for working it. M. Briant, by studying this point, succeeded in forging fine blades.

Experience has proved that the ordinary veins, called by the workmen *lignes* or *thorns* (*rincees*), which are seen upon the finest Eastern scymtars, are the result of the manner of forging them, as well as the method of twisting the Damascus steel. If these be drawn in length, the veins will be longitudinal; if they be drawn equally in all directions, the stuff will have a crystalline aspect. If they be drawn only in the two directions, undulated veins will be produced like those in the oriental Damascus.

The characteristics ascribed to the real Damascus blades are extraordinary keenness of edge, great flexibility of substance, a singular grain of fleckiness always observable on the surface, and a peculiar musky odour given out by any friction of the blade, either by bending or otherwise. The author of "*Manufactures in Metals*," remarks:

"A gentleman who purchased one of these blades in the East Indies for a thousand piastres, remarked to the writer of this volume that, although the instrument was very flexible, and bore a very keen edge, it could not with safety be bent to more than 45° from the straight shape, and it was not nearly so sharp as a razor, yet, wielded by a skilful hand it would cut through a thick roll of ~~raw~~ cloth without any apparent difficulty; a feat which could not be performed with an ordinary sword, nor, it should be observed, by the sabre itself in an ordinary hand, though the swordsmen who tried it could, it appears, do nearly the same thing with a good European blade."

Emerson, in his letters from the Aegean, says: "I have seen some blades (scymitars) which were valued at 200 or 300 dollars; many are said to be worth triple that sum, and all retain the name of *Damascus*, though it is by no means likely that they have been manufactured there. The twisting and intertwisting of the fibres of the metal are considered as the tests of excellence, but I have never seen any possessed of the perfume said to be incorporated with the steel in the real Damascus blade."

The production and use of damask steel has received much attention from the late General Anossoff, of the Corps of Engineers of the Imperial Russian army, and Master of the Fabric of Arms at Zlatoust, in Siberia. His researches and successful practice have become matters of history.

Steel helmets and cuirasses were formed of cast and damascened steel, intermixed with pure iron, a mixture supposed to combine toughness and hardness in greatest possible degree.

At different periods these works have been visited, separately, by two English travellers, Major Abbott of the Bengal Artillery, and Mr. Atkinson, who have recorded the results of observation, experiment, and conversational intercourse, and they state severally their conviction that the damask steel produced by Anossoff rivalled in beauty and excellence any works they had ever seen in other lands. They accord to Anossoff the honour of being the reviver of the art of making damask steel in Europe, while they declare the Russian natural damask steel is not approached by the fabrics of any Eastern nation now existing.

The Siberian swords and daggers were compared and tried with the choicest specimens, and found equal to the blades of Damascus, and the sabres of Khorsman; and while these valued articles might have been selected from numbers manufactured by chances of skill and material, Anossoff united chemical analyses of ores and steel, and records of observations on progressive stages, to give a true history of the means to explain and insure success. See SWORD MANUFACTURE.

DAMASCUS GUN-BARRELS. See GUN-BARRELS.

DAMASK is a variegated textile fabric, richly ornamented with figures of flowers, fruits, landscapes, animals, &c., woven in the loom, and is by far the most rich, elegant, and expensive species of ornamental weaving, tapestry alone excepted. The name is said to be derived from Damascus, where it was anciently made.

Damask belongs to that species of texture which is distinguished by practical men by the name of tweeling, of which it is the richest pattern. The twel of damask is usually half that of full satin, and consequently consists of eight leaves moved either in regular succession or by regular intervals, eight leaves being the smallest number which will admit of alternate tweeling at equal intervals.

The generic difference of tweeling, when compared with common cloth, consists in the intersections, although uniform and equidistant, being at determinate intervals, and not between the alternate threads. Hence we have specimens of tweeled cloth, where the intersections take place at the third, fourth, fifth, sixth, seventh, eighth, or sixteenth interval only. The threads thus deflecting only from a straight line at intervals, preserve more of their original direction, and a much greater quantity of materials can be combined in an equal space, than in the alternate intersection, where the tortuous deflection, at every interval, keeps them more asunder. On this principle tweeled cloths, of three and four leaves are woven for facility of combination alone. The coarser species of ornamented cloths, known by the names of dornock and Capet, usually intersect at the fifth, or half satin interval. The sixth and seventh are rarely used, and the intersection at the eighth is distinguished by the name of satin in common, and of damask in ornamental tweeling. It will further be very obvious, that where the warp and woof cross only at every eighth interval, the two sides of the cloth will present a diversity of appearance; for on one side the longitudinal or warp threads will run parallel from one end of a web to the other, and, on the other, the threads of woof will run also parallel, but in a transverse direction across the cloth,

or at right angles to the former. The points of intersection being only at every eighth interval, appear only like points, and in regular tweeling these form the appearance of diagonal lines, inclined at an angle of 45° (or nearly so) to each of the former.

The appearance, therefore, of a piece of common tweeled cloth is very similar to that of two thin boards glued together, with the grain of the upper piece at right angles to that of the under one. That of an ornamental piece of damask may, in the same manner, be very properly assimilated to a piece of veneering, where all the wood is of the same substance and colour, and where the figures assume a diversity of appearance from the ground, merely by the grain of the one being disposed perpendicularly to that of the other.

From this statement of the principle, it results that the most unlimited variety of figures will be produced, by constructing a loom by which every individual thread of warp may be placed either above or below the woof at every intersection; and to effect this, in boundless variety, is the object of the Jacquard mounting. See LOOM, JACQUARD.

The chief seat of this manufacture is the town and neighbourhood of Dunfermline, in Fifeshire, — and Lishorn and Arlonyne, near Belfast, where it is considered as the staple, having proved a very profitable branch of traffic to the manufacturer, and given employment to many industrious people.

The material used there is chiefly linen; but many have been recently woven of cotton, since the introduction of that article into the manufacture of cloth has become so prevalent. The cotton damasks are considerably cheaper than those of linen, but are not considered either so elegant or durable. The cotton, also, unless frequently bleached, does not preserve the purity of the white colour nearly so well as the linen.

DAMASKEENING; the art of ornamenting iron, steel, &c., by making incisions upon its surface, and filling them up with gold or silver wire; it is chiefly used in en-chasing sword blades, guards, and grips, locks of pistols, &c.

Its name shows the place of its origin, or, at least, the place where it has been practised in the greatest perfection, viz. the city of Damascus, in Syria; though M. Fellibien attributes the perfection of the art to his countryman, Carusnet, who wrought under the reign of Henry IV.

Damaskeening is partly mosaic work, partly engraving, and partly carving. As mosaic work, it consists of pieces inlaid; as engraving, the metal is indented, or cut in intaglio; and as carving, gold and silver are wrought into it in relief.

There are two ways of damaskeening; in the first, which is the most beautiful, the artists cut into the metal with a graver, and other tools proper for engraving upon steel, and afterwards fill up the incisions, or scratches, with a pretty thick silver or gold wire. In the other, which is only a perturbed, they connect themselves to make hatches, or strokes across the iron, &c., with a cutting knife, such as is used in making small files. As to the first, it is necessary for the graver or scratcher to be made in dove-tail form, that the gold or silver wire, which is thrust forcibly into them, may adhere the more strongly. As to the second, which is the more usual, the method is this: having heated the steel till it changes to a violet, or blue colour, they heat it over and across with a knife, then draw the engraving or ornament intended upon the hatching with a fine brass point or bodkin. Then done, they take fine gold wire, and connecting or chasing it according to the figures already designed, they work it carefully into the hatches of the metal with a copper tool.

An inferior description of damaskeen work has been introduced since the discovery of the electrotype process. The pattern has been etched on the steel, and then gold or silver deposited into the etched lines.

DAMASSIN. A kind of damask, with gold and silver flowers woven in the warp and woof, or occasionally with silk ornaments.

DAMP, in mining are dangerous exhalations, or rather gases, — so called from the German *dampf*, vapour — escaping from the mineral formations, or accumulating in the workings.

Fire-Damp, which occurs in coal mines, is carburetted hydrogen gas.
Choke-Damp, **After-Damp**, and **Black Damp**, may be regarded as Carbonic acid.
See MINES, ventilation of.

DAPHNINE. The bitter principle of the *Daphne alpestris*.
DASH WHEELS. These were revolving wheels having dash-boards, which are much used in the washing processes necessary in calico printing. See PRINTING.

DATHOLITE. Boracicate of lime, called also *Eamarkite* and *Hambroite*. It is found at Arrudal in Norway and in New Jersey.
Its chemical composition is, silica 37.50, boric acid 21.92, lime 35.77, water 5.71.

DATURINE. See ATROPINE.

DEAL WOOD. See PINUS.

DECANTATION. (Eng. and Fr.: *Abgießen*, Germ.) The act of pouring off the clear liquor from any sediment or deposit. It is much employed in the chemical arts, and it is frequently effected by means of a siphon, there being less risk of disturbing the precipitate.

DECKLE, name given by the paper maker to a thin frame of wood sitting on the shallow mould in which the paper pulp is placed.

DECOCTION. (Eng. and Fr.: *Zersetzung*, Germ.) The process of boiling a liquid with some organic body, or the liquid compound resulting from the process of boiling.

DECOMPOSITION. The separation of bodies from each other. The methods employed are almost innumerable, and usually depend on the special reactions of the matters under examination. We shall consider a few of the most striking cases in both the grand divisions of the science, viz. inorganic and organic chemistry. In each instance we shall, for the sake of convenience, subdivide into the three classes of acids, alkalies, and neutral bodies. Previous, however, to this, we must glance at some of the reactions of which chemists avail themselves in separating the elements. The decomposition of ordinary metallic salts, with the view of making a qualitative analysis of a more or less complex mixture, is a problem, in general, of extreme simplicity, and directions for the purpose are to be found in all the numerous works on qualitative analysis. The principle on which the modern methods of qualitative analysis are founded, is the separation of the metals in the first place into large groups by certain reagents, and then by means of others, to subdivide into smaller groups, in which the individual metals can be determined by special tests. For the sake of simplicity, we shall only consider the more commonly occurring metals. The general reagents, by which the first subdivision is effected, are hydrochloric acid, sulphuretted hydrogen, sulphide of ammonium, carbonate of ammonia mixed with chloride of ammonium, and finally phosphate of soda. The substance in solution is treated with hydrochloric acid, by which mercury, silver, and lead are removed. The mercury will only be perfectly removed if it exists entirely in the state of a subsalt. Lead is only partially precipitated, and will be subsequently found in the next group. The precipitate by hydrochloric acid is to be boiled with water, which will remove the chloride of lead, and leave the chlorides of mercury and silver. The latter may be separated by means of ammonia, which will dissolve the chloride of silver and convert the mercury into a black powder, in which the metal can be detected by special tests. The fluid filtered from the precipitate by hydrochloric acid, is to have a stream of hydrosulphuric acid gas passed through it for a considerable time, or until no more precipitation occurs. By this means antimony, arsenic, tin, cadmium, gold, mercury, silver, lead, bismuth, and copper are thrown down, and must be separated from each other by special processes. The filtrate from the precipitate by hydrosulphuric acid is to have ammonia added in slight excess, and then a solution of sulphide of ammonium as long as any precipitation takes place. By this means nickel, cobalt, iron, manganese, zinc, alumina and chromium, are thrown down; also baryta, strontia, and lime, if they happen to be in combination with phosphoric oxalic or boracic acids, or if united to fluorine. From the filtrate, carbonate of ammonia mixed with chloride of ammonium, precipitates baryta, strontia, and lime. The filtrate from the last precipitate can only contain magnesia, or the alkalies. The above brief description of the mode of dividing the metals into groups will be sufficient to give an idea of the processes employed for decomposing complex mixtures into simple ones.

Inorganic acids are usually removed from metals by converting the latter into an insoluble compound, while the acid remains in solution either in the free state or combined with a body of such a nature as not to mask the reactions of the acid with reagents. This is often done in the laboratory by boiling the metallic salt with an alkaline carbonate. The metals are, consequently, either converted into oxides or carbonates insoluble in water, while the acid unites with the alkali to form a soluble salt capable of being obtained by filtration in such a condition as to permit the nature of the acid to be made known by means of appropriate tests. It is usually necessary to neutralise the solution carefully before testing for the acid.

It is seldom necessary in researches to reduce inorganic alkalies to their elements, their constitution being usually ascertained by converting their constituents into new forms capable of being weighed or measured with accuracy. If, for instance, it was necessary to ascertain the constitution of sulphuric acid, it would be sufficient to determine the quantity of baryta contained in the sulphate. On the other hand, acids susceptible of assuming, when pure, the gaseous condition may have their constitution determined by decomposing a known volume with a substance capable of combining with one ingredient and liberating the other in the gaseous state. Thus hydrosulphuric acid may be analysed by heating it with potassium, which will remove the sulphur and liberate the hydrogen.

In decomposing inorganic alkalies with the view of separating the metals contained

in them, we usually have to avail ourselves of very powerful affinities. This arises from the fact, that the substances in question are, generally, produced by the union of a metal with oxygen, the metal having so strong a tendency to combine with that element, that mere exposure to the air is sufficient to determine their union into a compound of great stability. In order, therefore, to decompose the alkalies of this class, it is necessary to find some substance having a powerful tendency to combine with oxygen under certain conditions. Now it has been found that carbon, if raised to an exceedingly high temperature, and employed in great excess, is capable of removing the oxygen even from such bodies as potassium and sodium, the affinity of which for oxygen is very great.

Inorganic neutral bodies are generally decomposed either by the ordinary processes of analysis, or, where the neutrality arises from the substance under examination being a compound of an acid and a base, by separating the two by treatment with a reagent capable of combining with one to the exclusion of the other. This is a process frequently available in quantitative analysis. As an illustration, we may take the decomposition of the carbonates by a mineral acid in an apparatus which permits the carbonic acid set free to be accurately estimated by weighing. (See CARBONATES.) Another instance of the decomposition of a neutral body, by treating it with a substance capable of combining with one of the constituents and separating the other in a free state, is the decomposition of sulphate of potash by baryta. If a solution of the salt be boiled with excess of solution of baryta, sulphate of baryta is produced and caustic potash set free. The excess of baryta is removed by heating in the air until the whole of the latter base is converted into the insoluble carbonate. A precisely analogous process is the ordinary mode of preparing caustic potash by boiling its carbonate with quicklime.

Neutral bodies are frequently, however, so constituted, that the neutrality does not arise from the circumstance of an acid being saturated with a base, but from the energies of two elements being, to some extent, satisfied by the fact of their being in combination. Thus, water is a neutral substance, nevertheless it may be decomposed by a variety of processes, several of which are susceptible of quantitative precision. In the first place, it may be decomposed by passing steam over a metal capable of uniting with its oxygen with liberation of the hydrogen. It may also be electrolysed and the two gases separately obtained.

Organic or inorganic neutral salts may, at times, be very completely and simply decomposed by means of the battery. Not only are the various processes in electro-metallurgy founded on this principle, but it has even been practically applied to the quantitative estimation of the metals in ores. The electrolysis of the neutral salt of the great series of organic acids of the general formula $(C_nH_{2n}O_2)$ has thrown great light on some previously obscure points in the radical theory.

The decompositions and reactions by organic substances in contact with inorganic are so manifold, that the limits of this work preclude the possibility of doing more than glancing at a few of the most general and interesting. Perhaps of all the modes of inducing the breaking up of an ore complex into simpler substances, the application of heat is the most remarkable for its power and its varied and extensive effects on the substances produced. It has been shown that, as a decomposing agent, heat possesses an essential function. From complex organic molecules all classes of substances are formed. In various substances belonging to every chemical type are, therefore, found among products of destructive distillation. Acids, alkalies, and neutral bodies of every kind are formed, and some of the most interesting and beautiful bodies known to chemists are found in the uninviting looking tar of coal. Let us illustrate this by a glance at a few of the coal-tar products. Among the acids are the oxyphenic, carbonic, and cresylic. The alkalies represented are methylamine, ethylamine, propylamine, butylamine, amylamine, pyridine, quinoline, indoline, paroline, chinoline, lypine, erythrine and aniline. Among hydrocarbons are benzole, toluole, xylene, cumole, cymole, propylene, butylene, amylene, naphthalene, anthracene, chrysene, pyrene &c. &c. The list, probably, does not include one half of the substances produced from coal by the decomposing and recomposing influence of heat.

Mineral acids exercise a powerful decomposing influence on organic substances. Of these, the nitric and sulphuric are the most generally used. Nitric acid is especially active, owing to its twofold action. By virtue of its oxidising tendency, it breaks up great numbers of substances into more simple and less carbonized derivatives, and the hyponitric acid produced by the removal of one of the oxygens of the nitric acid frequently enters into the resulting compound, a substance which, being the final result. In the latter body is produced in this manner the hyponitric acid (N_2O_3). Generally replaces hydrogen, the original type remaining unaltered. The products of oxalic acid from sugar, succinic, lactic, adipic, trimellitic, &c. &c. from fatty

and fatty matters by the action of nitric acid, are examples of its oxidising power; while the formation of nitrobenzole, and bodies of more or less analogous character, present instances of the replacement of hydrogen by hyponitric acid.

Sulphuric acid owes its decomposing power to its extreme tendency to combine with water. Many of the less stable organic bodies are, by this means, absolutely broken up, so that the resulting products are of a character too indelicate to allow of the changes being expressed by an equation which shall render a true account of all the substances directly or indirectly formed. On the other hand, the action may be so controlled by the careful regulation of the temperature and strength of the acid that products may be eliminated which are themselves totally broken up and destroyed by an acid of greater strength. The production of grape sugar by the action of sulphuric acid on starch, or lignine, may be taken as an example. It not unfrequently happens, that the sulphuric acid unites with the substance acted on to form a conjugated compound. Benzole, and many other hydrocarbons, as well as oxidised bodies, behave in this manner with concentrated sulphuric acid.

Chlorine and the other halogens are powerful decomposing agents, acting chiefly by virtue of their affinity for hydrogen. The principal effects produced by them are oxidation and substitution. The oxidising action of the halogens arises from the decomposition of water; the hydrogen combining with the chlorine, &c., to form an hydracid, and the free oxygen uniting with the other substances present.

The above sketch will sufficiently indicate some of the most usual methods by which the decomposition of organic and inorganic bodies is effected; but hundreds of other decomposing agencies are at the call of the chemist, when any phenomena involving the disruptions of compounds are to be investigated. — C. G. W.

DECREPITATION (Eng. and Fr.; *Verknistern*, Germ.) is the crackling noise, attended with the flying asunder of their parts, made by several minerals and salts when heated. Sulphate of baryta, chloride of sodium, calcareous spar, nitrate of baryta, and several other bodies which contain no water, decrepitate most violently, separating at the natural joints of their crystalline structure.

DEFECATION. (Eng. and Fr.; *Klaren*, Germ.) The freeing from dregs or impurities.

DEFLAGRATION. (Eng. and Fr.; *Verpuffung*, Germ.) A rapid combustion, attended with much evolution of flame and vapour. When metals are burnt by electricity, they are said to undergo deflagration.

DEFLAGRATOR. A galvanic instrument for producing a rapid and powerful combustion, introduced by Professor Hare.

DE LAINES. Properly, fine worsted fabrics. They are indeed figured muslins, which should always be made of wool, but they are frequently made of mixed material.

DELFT. A coarse species of pottery originally manufactured at Delft in Holland, covered with a white enamel or glaze. See **POTTERY**.

DELIQUESCENT. (*Zerfließen*, Germ.) Any solid which absorbs moisture from the air spontaneously, and becomes soft or liquid; such as potash, and chloride of calcium.

DELPHINIA. The poisonous principle of the *Stavesacre*.

DEMY. Paper of a particular size is so called. Drawing demy is 15 inches by 20; printing demy is $17\frac{1}{4}$ inches by $22\frac{1}{4}$.

DENUDATION. (*Denudo*, to lay bare.) The carrying away by the action of running water of the superficial solid materials of the land, by which the lower rocks are laid bare.

DEODORISERS. Bodies which have the power of depriving fetid and offensive effluvia of their odours. There appears to exist a general idea that these substances are, all of them, equally disinfectants. No greater mistake can be made than to suppose that because a preparation has the power of removing a disagreeable smell, that therefore it has removed all the elements of infection or disease. See **DISINFECTANT**.

To disguise unpleasant odours, fumigation is employed, many of the fragrant gums are burnt, and fumigating pastiles employed. It is also a common practice to burn lavender and brown paper, but these merely overpower or disguise the smell; they do not in any way act upon the noxious effluvia. See **PASTILES**. **FUMIGATION**.

DEPHLEGMATION. The process by which liquids are deprived of their watery particles. It is applied chiefly to spirituous liquors, but is now obsolete, as involving the alchemical notion of a peculiar principle called *phlegm*.

DEPHLOGISTICATED, deprived of *phlogiston*, which was for a long period after the time of Stahl regarded as the principle of *levity* and of *combustion*. It may be regarded as synonymous with *oxygenated*. "Others believe that *Earth* and *Phlogiston* are those principles which are the constituent parts of all corporeal substances."

"It appears from all those experiments, that in each of them *phlogiston*, the simple inflammable principle, is present." "Thus much I see from the above mentioned

experiments: that air is composed of two different fluids, the one of which attracts not the phlogiston, and the other has the quality of attracting it."—*Scheele: Experiments on Air and Fire.*

DEPILATORIES. Preparations for removing hair from the skin. These are said to have been much used by the ancients. In modern times they have been used as cosmetics to remove superfluous hair from the face. Lime and the tersulphuret of arsenic (Orpiment) are the constituents of most of the ancient and modern depilatories; but the use of orpiment is dangerous, especially if there is any abrasion of the skin.

The best and safest depilatory is said, in *Gray's Supplement to the Pharmacopoeia*, edited by Hildrood, to be a strong solution of sulphuret (sulphur) of barium made into a paste with powdered starch. It should be applied to the hair immediately after it is washed, and allowed to remain there for five or ten minutes.

DEPOSITION OF METALS. See ELECTRO-METALLURGY.

DERBYSHIRE SPALL. Floor spar, or fluorside of calcium; which see.

DERRICK CRANE. The term Derrick is applied to a temporary crane, consisting of a spar supported by stays and guys, carrying a purchase for loading or unloading goods on shipboard. The Derrick crane is somewhat similar in its plan, the projecting iron beam, or derrick, of which can be raised or lowered to any desired angle.

DESICCATION. The act of drying.

Davison and Symington patented a process for drying or seasoning timber, by currents of heated air. Even after wood has been dried in the ordinary manner, it contains much moisture, which it is still necessary to remove. The patentees have given some curious results of this desiccating process.—

Temperature of air 214°.

Various wood.	Original weight.	Weight after seasoning.	Moisture removed.
6 pieces small and thin	3.38	2.87	8 per cent.
2 pieces larger	10.56	9.5	10.1 do
2 pieces larger	25.25	22.93	9.25 do

	Original weight.	1700 after 6 hours	1700 after 12 hours	1700 after 24 hours	1700 after 48 hours	1700 after 72 hours	Per cent.
Oak	1.64	1.76	1.71	1.59	1.26	1.31	18.1
Red pine	1.5	1.4	1.35	1.25	1.28	1.25	16.6
Birch	1.7	1.09	1.08	1.01	.99	.97	19.2
Mahogany	1.31	1.14	1.09	1.03	1.0	.98	19.3

White wood, lime tree.

	Original weight.	1700 after 6 hours	Part 1600, and part 3100 after 15 hours	After 24 hours.	After 24 hours.	After 24 hours.	Per cent.
1	18.5	20.45	18.7	18.22	17.4	17.1	26.
2	25.19	21.33	19.87	18.9	18.17	18.0	28.5
3	23.67	19.7	17.83	17.6	16.82	16.73	29.2
4	20.04	17.07	15.8	15.6	15.13	15.03	25.

No. 3 exposed to the atmosphere for three weeks, weighed at the end of that time 17.8, or had taken in 4.2 per cent. of moisture.

Feathers. Feather beds, mattresses, blankets, and clothing, are not only dried, but purified by this process. A feather bed of sixty pounds weight, will have no less than 100,000 cubic feet of air passed through it; and at the same time heaters are made use of, for the purpose of removing the dust. Feathers treated in this manner have their

• It will be observed, on referring to the last column of the table, that the wood, although kept in the chamber exposed to heated currents for 72 hours, weighed nothing less after the first 24 hours, than (No. 1, 2, &c.). The application of the desiccating process for timber is to expose it for some hours to the heated currents of air, and then, in its heated state, immersing it suddenly in any of the various mixtures, creosote or coal-tar. The result is, that the air-vessels of the wood, and the pores of the wood, are charged with the solid substance in which the wood is immersed.

bulk and elasticity so much increased, that a second tick is found almost invariably necessary in put the feathers into.

A practical proof of the extreme powers of currents of dry heated air was given in Syria, by exposing to them sixty suits of clothes, which had belonged to persons who died of the plague. These clothes were subjected to the process alluded to, at a temperature of about 240° , and afterwards worn by sixty living persons, not one of whom ever gave the slightest symptom of being in the slightest degree affected by the malady. (Hishaw.) The purification of feathers by this process is carried out in many large establishments. Coffee it has been proposed to dry by currents of heated air, and subsequently to roast it by the same process.

Thick card-board, used for tea-trays and papier maché, is now frequently dried by heated air. By the plan adopted at one establishment, previously to the introduction of Davison and Symington's method, it invariably occupied from eighteen to twenty hours to dry a room full of paper by a heating surface equal to 330 feet; whereas by the new method, the same amount of work is accomplished in four hours, and with a heating surface of only 44 feet, or one seventh the area required by the former.

Silk.—For the purpose of drying silk, it has been usual to heat the drying chambers by large cast-iron globular stoves, the heat obtained thus was equal to 120° F., but excessively distressing to any stranger entering these apartments.

In one arrangement 7000 cubic feet per minute are admitted at the above temperature through small perforated iron plates, let into the stone floor. As many as 3000 pieces of silk are sometimes suspended at one time; and as each piece of silk, when wet contains about seven ounces of water, and as the operation of drying the whole occupies but one hour, it follows that about 130 gallons of water are evaporated in that time.

Yarns.—In Scotland and other places they now dry yarns by modified applications of this process; and it is indeed extensively used in bleaching establishments, in calico-printing works, &c. See *Transactions of the Society of Arts for 1847-8*.

A DRYING HOUSE is an apartment fitted up in a peculiar manner for drying calicoes, and other textile fabrics. Mr. Southworth, of Sharples, a Lancashire bleacher, obtained a patent in 1823, for the following ingenious arrangement, which has been since generally adopted, with certain modifications, in most of our extensive bleaching and printing works. *Fig. 641*, is a section of the drying-house, where *a* is a furnace and boiler for the purpose of generating steam; it is furnished with a safety valve in the tube *b*, at top, and from this tube the steam main *c* passes down to the floor of the basement story. From this main, a series of steam-pipes, *and d*, extends over the surface of the floor, and from them heat is intended to be diffused for the purpose of warming the drying-house.

Along the middle of the building a strong beam of timber *e e* extends, and is supported by cast-iron pillars; from this beam, to hearings on the side walls, a series of rails are carried in a cross direction, over which rails the wet cloth is to be hung in folds, and the steam or evaporation emitted in drying is allowed to escape through apertures or ventilators in the roof.

The mode in which the cloth is delivered on to the rails, on either side of the beam will be best understood by reference to the delivering carriage, which is shown, with its rollers partly in section.

The wet cloth is first to be coiled upon a roller, and then placed in the carriage, as at *f*, with its pivots bearing upon inclined planes. The carriage is to be placed at the commencement of the rails, running upon the middle beam, and also upon the side-bearings or railways extending along the side walls of the building, parallel to and upon a level with the same beam. It is made to travel by means of an endless band passing over two riggers *g* and *h*, in *fig. 604*, and over pulleys and a band-wheel attached to the carriage, as will be explained. The rigger *g*, which moves this endless band, is actuated by bevel gear, seen at *b*, which is put in motion by a pinion at the end of a revolving shaft leading from a steam engine.

In the same *fig.*, *k k*, is the endless band passing over a pulley under the band-wheel, and over the pulley *a*, by which it will be perceived that the traversing of the band, as described, would cause these pulleys and wheels to revolve. On the action of the band-wheel *m*, there is a drum against which the roll of wet cloth *f* presses, and as this drum revolves, the roll of wet cloth is, by its friction, made to turn in a contrary direction, and to deliver off the cloth on to the periphery of the drum, whence it passes over a roller and descends to the rails. Upon the end of the axle of the band wheel *m*, there is a pinion which takes into the teeth of the large wheel, and upon the axle of this large wheel there is a pinion that actuates the intermediate wheel which turns another toothed wheel. This last mentioned toothed wheel takes into cogs upon the side railway, and hence, as the train of wheels moves round, the carriage to which the wheels are attached is slowly impelled forward.

As soon as the wheels begin to move, and the carriage to advance, the wet cloth begins to uncoil, and to pass down over the first roller: a small roller attached to the carriage, as it passes over the rail in succession, holds the cloth against each rail for a short space of time, and prevents it from slipping, by which means the cloth descends in folds or loops between the rails, and is thereby made to hang in a series of folds or loops as shown in the figure.

It will be perceived that as the pivots of the cloth roller *f* bear upon inclined planes, the roller will continually slide down as the cloth diminishes in bulk, keeping in contact with the drum, and delivering the cloth from the roller on to the several rails, as described.

In order to stop the carriage in any part of its course, or to adjust any of the folds of the cloth, a man is usually placed upon the platform travelling with the carriage, over which he has perfect command. This apparatus may be also employed for taking the

641

cloth when dried off the rails: in which case the carriage must be made to travel backwards, and by first guiding the end of the cloth on to the roller *f*, and then putting the wheels in a retrograde motion, the cloth will be progressively wound upon the roller *f*, in a similar way to that by which it was unwound.

DRYING MACHINE (CONTINUOUS). (*Machine à sécher, M. continue, Fr.*)
By this contrivance, I've sold: was enabled to improve all kinds of wet clothes with the

642

minutes of their moisture, without compression or heat. Kelly, a dyer, and A. and a bleacher, have since obtained a patent for the above machine with improvements. Fig. 642, represents a partial section of the machine. A, A, is the frame. B, the

vertical shaft turning in the step *a*, fixed on the bridge *b*. This shaft bears on its upper part a friction cone *c*, from which it receives its movement of rotation, as will be presently shown; *c* is a drum containing two concentric compartments *d* *e*, of the form represented in the figure; this drum moves freely upon the shaft *n*, and rotates when it is not in motion upon two conical projections *f* *g*, which form a part of the shaft. These two compartments are each composed mainly of metal, and their sides consist of tinned iron wire coiled circularly at very small distances from each other, and soldered together crosswise by small strips of metal. The top which covers the inner compartment *d*, is secured by bolts and screws to a circle of iron which retains the wire sides of the same metal, but that which serves as a cover to the little compartment *e*, in which alone the goods are placed, is disposed so that it may be removed with ease, when these are to be introduced or withdrawn. It is furnished with an outer and inner border, disposed so that when the top is fixed the inner border presses upon the convex circumference of the central compartment, while the exterior border falls outside of the edges of the other compartment. While the machine is at work, the second plate is maintained in its place by pins or bolts, not shown in the figure.

The sides of the outer compartment *d*, are connected with the bottom by means of a prolongation of cross bands of metal which unite the wires and are riveted or soldered to the two outer plates. The wires of the interior compartment are attached by an iron hoop, to which they are riveted and soldered, and are united to the bottom plate by means of a rim upon this plate; a rim somewhat flattened upon the sides which are riveted and soldered.

n, is a regulator suspended in the inner compartment *d*, and whose two branches *h* *h*, are loaded. These two branches having room to play around the bolts which serve as points of attachment, and which are fixed to the upper plate, terminate in knood branches whose extremities rest upon a rope *g*, which projects from the shaft. *r*, is an exterior envelope secured to the frame *A*, *A*. It encloses the whole drum except at top, and serves to catch the water thrown out of the goods. At *y* there is a stop cock for the discharge of this water, and the bottom contains besides the end of a pipe by which hot air is introduced.

The vertical shaft *n* receives a movement of rotation and carries with it the drum. The more rapid this movement is the more does the centrifugal force tend to expel the water contained in the clothes or yarn to be dried. But as this force might also displace the central shaft, if the weight was not rightly distributed in the drum, and cause the dislocation of the machine when the great velocity requisite for quick drying is given to it, the regulator *n* is tested to prevent accident. The branches of this regulator spread wider the more the velocity is increased, and raise consequently the drum *c* above the conical enlargements, which permits the drum to be somewhat misplaced and to rectify its position conformably to the inequalities of its load, so that its centre of gravity may always coincide with its centre of rotation. The drum is connected with the shaft as is shown in *z*, leaving it free to take the requisite adjustment. To hinder it from rising too suddenly, a spiral spring *k* is fixed over the shaft immediately above the conical enlargement *g*. In order to maintain the equilibrium more certainly, the apparatus is surrounded with a hollow crown *v*, half filled with water, and if during the revolution of the machine the weight of the goods predominates on one side, that of the water which accumulates on the other side serves the more to counterbalance it. The effect of this crown may be increased by dividing it into two compartments or more. *a*, is a large pipe by which steam or hot air is introduced into the belly of the drum, which is pierced in this place with a great number of small holes to receive it.

The rotary movement is transmitted to the drum in the following way.

1, is a conical disc mounted upon the extremity of a shaft *k'* which actuates the cone *c* and the shaft *n* by means of friction; 1' is a cone fixed upon the extremity of the shaft. *k''* 1'' is another cone of the same dimension, but whose base fronts the top of the other, and which is placed on the shaft *k''* commanded by the prime mover. *x* is the belt which embraces the two cones, and whose lateral displacement, effected by means of a fork, permits the velocity of the machine to be regulated at pleasure. *x* is the pulley which directly receives the movement. In place of a single friction disc 1, another may be employed, if judged necessary, and placed between the two, an additional friction pole, in order better to equalise the friction. In this case the disc and additional cone should turn freely upon their own shafts. We may also adopt another arrangement for the bottom of the vertical shaft. The shaft immediately above the step is surrounded by a loose rim, around which a certain quantity of lead shot, or other granular matter, is contained in the rim in the box which serves for the step. The top of this box is pierced with an opening, into which, when the machine is at rest, a cord connected with the shaft sinks, controlled by the shaft, and when

the drum is raised by the action of the regulator *n*, this cord quits its place, which allows the shaft to displace the shot a little, and to take a position conformably to the point of the centre of gravity.

But after all great attention should be paid to the proper working of the machine. There are many other drying machines used, some of which are described in the articles devoted to special manufactures.

DETONATION. See **FULMINATION**, for the mode of preparing detonating powder for the percussion caps of fire-arms.

DETRETTUS; *de, from, trer, to rub.* Matter worn off rocks, and deposited in valleys.

DEUTOXIDE, literally means the second oxide, but is usually employed to denote a compound containing two atoms or two prime equivalents of oxygen to one or more of a metal. Thus we say deutoxide of copper, and deutoxide of mercury. Hence we abbreviate this expression by adopting the principles of the French nomenclature of 1787; according to which the higher stage of oxidisation is characterised by the termination *ic*, and the lower by *ous*. It is now rarely employed.

DEVIL. The name of a spiked mill, used in Yorkshire, for testing woollen rags into fragments for the manufacture of Snopur.

DEVONSHIRE BATTS. A porous fine-grained sandstone from the quarries of Black Down Cliffs, near Collumpton, in repute as a grindstone.

DEVONSHIRE OIL-STONE. This stone occurs near Hoel Friendship Mine, about three miles from Tavistock, in the Devonian Slates of that district. It has considerable local repute for sharpening all kinds of thin-edged broad instruments: it has not, however, become an article of commerce. — *Knight, Trans. Society of Arts.*

DREW-BUTTING. See **FLAX**.

DEXTRINE. Star h Gum. There are three modes of obtaining this from starch, viz., by torrefaction, by the action of dilute acids, and by the action of *diamine*. The impure dextrine obtained by roasting is termed *roasted starch*, or *leucome*. British gum is prepared by carefully roasting wheat starch, at a temperature of 300° Fabr. Another method of preparing dextrine consists in moistening 1000 parts of potato starch with 300 parts of water, to which 2 parts of nitric acid have been added. The mixture is allowed to dry spontaneously, and is afterwards heated for two or three hours in a stove, at 212° Fabr. Dextrine in many of its characters resembles ordinary gum, but it is distinguishable from it by its *right-handed rotation of a ray of plane polarised light*,—hence its name *dextrine*,—and by its yielding oxalic acid, but not mucic acid, when heated with nitric acid. Its chemical formula is $C_{12}H_{22}O_{11}$.

DIACINIC LENS. A name proposed to be given to the best construction of lens for the photographic camera obscura. It should be transparent to all the chemical rays, or rather, a lens which should unite the chemical and luminous foci in one point. The name has not been generally adopted.

DIALLAG. *Hornite, Hyperstene, and Schillerstein* are often confounded under this name. The name is derived from *diallagos*, *differre*, alluding to their cleavage. It is thin, foliated, and easily cleavable: laminæ brittle; colour, various shades of green, grey, and brown, sometimes bronze and pearly metallic.

Of diallag rock fine examples will be found near the Lizard Point, and in the crystals of diallag are to be discovered in the Serpentine rocks near Cadgwith, in the same locality.

DIAMAGNETISM. As this term is becoming more generally used in our language, it appears necessary to give a definition of it, although it is not our purpose to enter on the consideration of any purely physical subject.

The term was introduced by Dr. Faraday, to express those bodies which did not act as magnetic bodies do. If *a* and *c* represent the poles of a horse-shoe magnet, any bar of a magnetic character, as iron, cobalt or nickel, hung up between them and free to move, will by virtue of the attracting and repelling polar forces, place itself

613

NO 

along the line joining the two poles *a* & *b*, which is called the magnetic axis. If instead of a bar of iron we suspend in the same manner a rod of glass, of bismuth, or of silver, it will arrange itself equatorially, or across the line *a* & *b*, as shown by the dotted line, *e* & *d*. All bodies in nature appear to exist in one of those two conditions. The prefix *dia* is used here in the same sense as in diameter. See *De La Rive's Electricity*, for a full explanation of all the *diamagnetic phenomena*.

DIAMOND (*Diamant*, Fr.; *Diamant*, Germ.) Experiment has determined that

this beautiful gem is a peculiar (*allotropic*) condition of carbon. By burning the diamond in oxygen gas we produce carbonic acid; and by enclosing the gem in a mass of iron, and subjecting it to a strong heat, the metal is converted into steel, when the diamond has disappeared. It has been shown that we can, by the agency of the heat of the voltaic arc, convert the diamond into excellent coke, and into graphite; but although portions of coke are found to be sufficiently hard to cut glass, we have not yet succeeded in making diamonds from coke. Sir Humphry Davy noticed that the charcoal of one of the poles of Mr. Children's great voltaic battery was considerably hardened, and he regarded this as an advance towards the production of that gem. Recently some experiments made by a French philosopher have advanced the discovery another step: one of the poles of a voltaic battery being charcoal and the other of platinum, it was found that the fine charcoal escaping from the carbon pole and depositing itself on the platinum pole was sufficiently hard to be used in the place of diamond dust for polishing gems. The formation of the diamond in nature is one of the problems which "our philosophy" has not yet enabled us to solve. Time is an element which enters largely into nature's works; she occupies a thousand, or even thousands of years to produce a result, while man in his experiments is confined to a few days, or a few years at most.

Although diamonds have been occasionally found in various parts of the globe, there are only two places which can be strictly named as diamond districts, a portion of the Indian Peninsula and Brazil. India has been celebrated from the most remote antiquity as the country of diamonds. Its principal mines are in the kingdoms of Golconda and Visapour extending from Cape Connorin to Bengal, at the foot of a chain of mountains called the *Orissa*, which appear to belong to the trap rock formation. In all the Indian diamond soils, these gems are so dispersed that they are rarely found directly, even in searching the richest spots, because they are enveloped in an earthy crust, which must be removed before they can be seen. The stony matter is therefore broken into pieces, and is then, as well as the looser earth, washed in basins scooped out for the purpose. The gravel thus washed is collected, spread out on a smooth piece of ground, and left to dry. The diamonds are now recognised by their sparkling in the sun, and are picked out from the stone.

Diamonds are also said to come from the interior of the island of Borneo, on the banks of the river Succadan, and from the peninsula of Malacca. It is said the principal spots where diamonds are found are recognised by certain small flints, generally of a black colour, which lie upon the surface, and also by the yellow colour of the stony soil. The ground is dug in the presence of an overseer: all stones above 5 carats, are claimed for the sovereign. Diamonds are found occasionally in the rivers, seldom however of any size.

The diamond mines of Brazil were discovered in 1729, in the district of *Serro-do-Frio*. The ground in which they are imbedded has the most perfect resemblance to that of the East Indies where the diamonds occur. It is a solid or friable conglomerate, consisting chiefly of a ferruginous sand, which encloses fragments of various magnitude of yellow and bluish quartz, of schistose, Jasper, and grains of gold disseminated with oligist iron ore,—all mineral matters different from those that constitute the neighbouring mountains; this conglomerate, or species of pudding-stone, almost always superficial, occurs sometimes at a considerable height on the mountainous table-land. The most celebrated diamond mine is that of *Mandagari*, on the *Jigtonhonha*, in the district of *Serro-do-Frio* to the north of *Rio-Janeira*. The river *Jigtonhonha*, three times broader than the Seine at Paris, and from 3 to 9 feet deep, is made nearly dry, by drawing the water off with sluices at a certain season; and the *cascalho*, or diamond gravel, is removed from the channel by various mechanical means, to be washed elsewhere at leisure. This *cascalho*, the same as the matrix of the gold mines, is collected in the dry season, to be searched into during the rainy; for which purpose it is formed into little mounds of 15 or 16 tons weight each. The washing is carried on beneath an oblong shed, by means of a stream of water admitted in determinate quantities into boxes containing the *cascalho*. A negro washer is attached to each box; inspectors are placed at regular distances on elevated stools, and whenever a negro has found a diamond, he rises up and exhibits it. If it weighs $1\frac{1}{2}$ carats, he receives his liberty. Many precautions are taken to prevent the negroes from secreting the diamonds. Each squad of workmen consists of 200 negroes, with a surgeon and an almoner or priest.

The flat lands on either side of the river are equally rich in diamonds over their whole surface, so that it becomes very easy to estimate what a piece of ground not yet washed may produce.

It is said that the diamonds surrounded by a greenish crust are of the *first water*, or are the most limpid phenon. The diamonds received in the different mines of the district, are deposited once a month in the treasury of *Tejaco*; and the amount of what

was thus delivered from 1801 to 1806, may be estimated at about 18 or 19 thousand carats per annum.

On the banks of the torrent called Rio-Pardo, there is another mine of diamonds. The ground presents a great many friable rocks of pumice-stone, distributed in irregular crata. It is chiefly in the bed of this stream that masses of cascabel occur, peculiarly rich in diamonds. They are much esteemed, particularly those of a greenish-blue colour. The ones that accompany the diamond at Rio-Pardo differ somewhat from those of the washing grounds of Mandanga, for they contain no pisiform iron ore; but a great many pebbles of slaty jasper. This table land seems to be very high, probably not less than 2,500 feet above the level of the sea.

Tocaya, a principal village of Minas-Novas, is 34 leagues to the north-east of Tijuca, in an acute angle of the confluence of the Jigitonhonha and the Rio-Grande. In the bed of the streamlets which fall westward into the Jigitonhonha, those rolled white topazes are found which are known under the name of *minas novas* with blue topazes, and aquamarine beryls. In the same country are found the beautiful cyano-haies or chrysoberyls so much prized in Brazil. And it is from the cantons of Indaia and Abaita that the largest diamonds of Brazil come; yet they have not so pure a water as those of the district of Serrão-do-Frio, but incline a little to the lemon yellow.

It is known that many minerals become phosphorescent by heat or exposure to the sun's light. Diamonds, it has been said on doubtful authority, possess this property, but all not in equal degree, and certain precautions must be observed to make it manifest. Diamonds need to be exposed to the sunbeam for a certain time in order to become self-luminous; or to the blue rays of the prismatic spectrum, which augment still more the faculty of shining in the dark. Diamonds susceptible of phosphorescence exhibit it either after a heat not raised to redness, or the electric discharge. Many minerals possess the power of becoming electrically phosphorescent, which do not appear to be affected by the solar rays. Diamonds possess not only a great refractive power in the mean ray of light, but a high dispersive agency, which enables them to throw out the most varied and vivid colours in multiplied directions.

Diamonds take precedence of every gem for the purpose of dress and decoration; and hence the price attached to those of a pure water increases in so rapid a proportion, that, beyond a certain term, there is no rule of commercial valuation. The largest diamond that is known seems to be that of the Rajah of Mattan in the East Indies. It is of the purest water, and weighs 367 carats, or, at the rate of 4 grains to a carat, upwards of 3 ounces troy. It is shaped like an egg, with an indented hollow near the smaller end; it was discovered at Landak about 100 years ago; and though the possession of it has cost several wars, it remained in the Mattan family for 90 years. A governor of Batavia, after ascertaining the qualities of the gem, wished to be the purchaser, and offered 150,000 dollars for it, besides two war brigs with their guns and ammunition, together with a certain number of great guns, and a quantity of powder and shot. But this diamond possessed such celebrity in India, being regarded as a talisman involving the fortunes of the Rajah and his family, that he refused to part with it at any price.

The Mogul diamond passed into the possession of the ruling family of Kabul, as has been invariably affirmed by the members of that family, and by the jewellers of Delhi and Kabul. It has been by both parties identified with the great diamond now known under the name of the Koh-i-Noor, or mountain of light, — which was displayed by its present proprietor, her Majesty the Queen, at the Great Exhibition in 1851.

The diamond denominated the Koh-i-Noor, or Mountain (koh) of Light (noor), has long enjoyed both Indian and European celebrity, and has accordingly been the subject of traditional fable, as well as of historical record.

According to Hindu legend, it was found in the mines of the south of India in the days of the Great War, the subject of the heroic poem, the *Mahabharata*, and was worn by one of the warriors who was slain on that occasion, Karna, king of Anga. This would place it about 4000 years ago, or 2100 B.C. A long interval next makes it the property of Vikramaditya, the raja of Mijayn, 50 A.C., from whom it descended to his successors, the rajahs of Malwa, until the principality was subverted by Mohammedan conquerors, into whose hands it fell, with other spoils of Indian empire.

Whatever may be thought of the legend which gives so high an antiquity to the Koh-i-Noor, we might expect some more trustworthy information when we come down as low as the beginning of the fourteenth century; Malwa having been invaded and overrun by the armies of Ala-ud-din, the sultan of Delhi, in 1206, who, according to the autobiography of the sultan Baber, acquired the jewel. That it had become the property of the sultans of Delhi is little doubtful, but when or how it came to be so is uncertain, although the grounds of the difficulty have not hitherto been investigated.

In 1665 Mons. Jean Baptiste Tavernier, an enterprising and intelligent traveller, and an eminent Jeweller, although Ecuyer, Baron d'Anboune, visited India especially to purchase diamonds. His profession and his personal character seem to have recommended him to the favourable attention of the nobles of the court of Delhi, and he got as he was, of Aurangzeb himself, by whose commands Mons. Tavernier was permitted to inspect, handle, and weigh the jewels of the imperial cabinet. Amongst them was one which far surpassed all the rest in size and value. Tavernier describes it as rose-cut, of the shape of an egg cut in two, of good water, and weighing 319 $\frac{1}{2}$ ratas, which, he says, is equal to 280 of our carats.

There is but little doubt that the diamond examined by Tavernier in the Delhi Cabinet was the Koh-i-Noor. Baber, the Mogul emperor, obtained a diamond, corresponding exactly with this, and it passed eventually into the possession of the ruling family of Kabul. Nadir Shah, on his occupation of Delhi in 1739, compelled Mohammed Shah, the great-grandson of Aurangzeb, to give up to him everything of value that the imperial treasury possessed, and his biographer and secretary specifies a *peshkash*, or present, by Mohammed Shah to his conqueror of several magnificent diamonds. According to the family and popular tradition Mohammed Shah wore the Koh-i-Noor in front of his turban at his interview with his conqueror, who insisted on exchanging turbans in proof of his regard. However this might have been, we need have little doubt that the great diamond of Aurangzeb, was in the possession of Mohammed Shah at the time of the Persian invasion; and if it was, it must certainly have changed masters, and became, as is universally asserted, the property of Nadir Shah, who is also said to have bestowed upon it the name of Koh-i-Noor. After his death, the diamond which he had wrested from the unfortunate representative of the house of Timur, became the property of Ahmed Shah, the founder of the Abdali dynasty of Kabul, having been given to him, or more probably taken by him, from Shahzikh, the young son of Nadir. The jewel descended to the successors of Ahmed Shah, and when Mr. Elphinstone was at Peshawur, was worn by Shah Shuja on his arm. When Shah Shuja was driven from Kabul, he became the nominal guest and actual prisoner of Ranjet Sing, who spared neither importunity nor menace, until, in 1813, he compelled the fugitive monarch to resign the precious gem, presenting him on the occasion, it said, with a lakh and 25,000 rupees, or about 12,000*l*. sterling. According to Shah Shuja's own account, however, he assigned to him the revenues of three villages, not one rupee of which he ever realised. Ranjet was highly elated by the acquisition of the diamond, and wore it as an armlet at all great festivals. When he was dying, an attempt was made by persons about him to persuade him to make the diamond a present to Jagannath, and it is said that he intimated assent by an inclination of his head. The treasurer, however, whose charge it was, refused to give it up without better warrant, and Ranjet dying before a written order could be signed by him, the Koh-i-Noor was preserved for awhile for his successors. It was occasionally worn by Rhurrukh Sing and Shin Sing. After the murder of the latter, it remained in the Lahore treasury until the supercession of Dholp Sing, and the annexation of the Punjab by the British Government, when the civil authorities took possession of the Lahore treasury, under the stipulations previously made, that all the property of the state should be confiscated to the East India Company, in part payment of the debt due by the Lahore government and of the expenses of the war; it was at the same time stipulated that the Koh-i-Noor should be presented to the Queen of England. Such is the strange history of certainly one of the most extraordinary diamonds in the world. After the Company became possessed of the gem, it was taken in charge by Lord Dalhousie, and sent by him to England in custody of two officers.—*Hunt's Handbook of the Great Exhibition of 1851*.

As exhibited at the Crystal Palace in Hyde Park, the Koh-i-Noor weighed 186 $\frac{1}{2}$ carats.

The form of the Koh-i-Noor is given in *fig. 644*. *r* is a large plane at the base of the diamond which is a cleavage plane. *s*, also a large cleavage plane, produced by a fracture; this had not been polished, and being inclined to the plane *r* at an angle of 109° 28', affords a satisfactory means for determining the direction of the cleavage planes of the stone. *a* shows a flaw running parallel to the cleavage plane *r*. This constituted the principal danger to be apprehended in cutting the stone, and was most skilfully ground nearly out before any of the facets were cut. This flaw seemed to proceed from a fracture marked *a*. *c* and *e* were little notches cut in the stone for the purpose of holding the diamond in its original setting; *x* a small flaw which almost required a glass to see it, evidently parallel to the plane *r*; *d* a fracture from a blow or fall, showing at its base a cleavage plane.—*Tennant*.

This fine diamond did not possess that high degree of brilliancy which was expected from its great reputation; it was consequently submitted to Messrs. Garrard to be recut. In the operation the weight was reduced more than one-third, but its brilliancy

was greatly improved. The present state of the Koh-i-Noor is shown in *figs. 643 and 646*. See DIAMOND-CUTTING.

After this gem, the next are:—1. That of the emperor of Russia, bought by the late empress Catharine, which weighs 193 carats. It is said to be of the size of a pigeon's egg, and to have been bought for 30,000*l.*, besides an annuity to the Greek merchant of 4,000*l.* It is reported that the above diamond formed one of the eyes of the famous statue of Sheridan, in the temple of Brama, and that a French grenadier, who had deserted into the Malabar service, found the means of robbing the pagoda of this precious gem, and escaped with it to Madras, where he disposed of it to a ship captain for 2,000*l.*, who resold it to a Jew for 12,000*l.* From him it was transferred for a large sum to the Greek merchant. 2. That of the emperor of Austria, which weighs 139 carats, and has a slightly yellowish hue. It has, however, been valued at 100,000*l.* 3. That of the French State, called the Regent or Pitt diamond, remarkable for its form and its perfect simplicity. Although it weighs only 136 carats, its fine qualities have caused it to be valued at 160,000*l.*, though it cost only 100,000*l.*

The largest diamond furnished by Brazil, now in possession of the Crown of Portugal, weighs, according to the highest estimates, 120 carats. It was found in the streamlet of Abaité, in a clay-slate district.

Diamonds possessed of no extraordinary magnitude, but of a good form and a pure water, may be valued by a certain standard rule. In a brilliant, or rough diamond of regular proportions so much is cut away that the weight of the polished gem does not exceed one-half the weight of the diamond in the rough state; whence the value of a cut diamond is estimated equal to that of a similar rough diamond of double weight exclusive of the cost of workmanship. The weight and value of diamonds reckoned by carats of 4 grains each; and the comparative value of two diamonds of equal quality, but different weights, is as the squares of these weights respectively. The average price of rough diamonds that are worth working, is about 2*l.* for one of a single carat; but as a polished diamond of one carat must have taken one of two carats, its value in the rough state is double the square of 2*l.*, or 8*l.* Therefore to estimate the value of a wrought diamond, ascertain its weight in carats, double that weight, and multiply the square of this product by 2*l.* Hence, a wrought diamond of

1 carat is worth	£8	7 carats is worth	£784
2 " "	32	8 " "	512
3 " "	72	9 " "	612
4 " "	128	10 " "	800
5 " "	200	20 " "	3200
6 " "	288		

beyond which weight the price can no longer rise in this geometrical progression, from the small number of purchasers of such expensive toys. A very trifling spot or flaw of any kind lowers exceedingly the commercial value of a diamond.

Diamonds are used not only as decorative gems, but for more useful purposes, as for cutting glass by the glazier, and all kinds of hard stones by the lapidary.

On the structure of the glazier's diamond we possess some very interesting narra-

ations and reflections by Dr. Wollaston. He remarks, that the hardest substances brought to a sharp point scratch glass, indeed, but do not cut it, and that diamonds alone possessed that property; which he ascribes to the peculiarity of its crystallisation in rounded faces, and curvilinear edges. For glass-cutting, those rough diamonds are always selected which are sharply crystallised, hence called diamond sparks; but cut diamonds are never used. The inclination to be given to a set diamond in cutting glass is comprised within very narrow limits; and it ought, moreover, to be moved in the direction of one of its angles. The curvilinear edge adjoining the curved faces, entering as a wedge into the furrow opened up by itself, thus tends to separate the parts of the glass; and in order that the crack which causes the separation of the vitreous particles may take place, the diamond must be held almost perpendicular to the surface of the glass. The Doctor proved this theory by an experiment. If, by suitable cutting with the wheel, we make the edges of a spinel ruby, or corundum-telesie (sapphire), curvilinear, and the adjacent faces curved, these stones will cut glass as well as a glazier's diamond, but being less hard than it, they will not preserve this property so long. He found that upon giving the surface of even a fragment of flint the same shape as that of the cutting diamond, it acquired the same property; but, from its relative softness, was of little duration. The depth to which the fissure caused by the glazier's diamond penetrates does not seem to exceed the two-hundredth of an inch.

The following remarks by Mr. Tennant cannot fail to be of interest, and, as pointing out the errors which have been frequently committed through ignorance, of great value.

"By attending to the forms of the crystal, we are quite sure that we shall not find the emerald, sapphire, zircon, or topaz in the form of a cube, octahedron, tetrahedron, or rhombic dodecahedron; nor the diamond, spinel, or garnet in that of a six sided prism, and so on with other gems. For want of a knowledge of the crystalline form of the diamond a gentleman in California offered 200*l.* for a small specimen of quartz. He knew nothing of the substance, except that it was a bright shining mineral, excessively hard, not to be scratched by the file, and which would scratch glass. Presuming that these qualities belonged only to the diamond, he conceived that he was offering a fair price for the gem; but the owner declined the offer. Had he known that the diamond was never found as a six-sided prism, terminated at each end by a six-sided pyramid, he would have been able to detect the fact that what he was offered 200*l.* for, was really not worth more than half a crown."—*Tennant's Lecture on Gems.*

The accompanying forms may serve to guide those who are ignorant of crystallography.

The following technical terms are applied to the different faces of diamonds:—
Bezil: the upper sides and corners of the brilliant, lying between the edge of the table and the girdle.

Collet: the small horizontal plane or face, at the bottom of the brilliant.

Crown: the upper work of the rose, which all centres in the point at the top, and is bounded by the horizontal ribs.

Facets: small triangular faces, or planes, both in brilliants and roses. In brilliants there are two sorts, *skill* or *skill-facets*, and *star-facets*. Skill-facets are divided into *upper* and *under*. Upper skill facets are wrought on the lower part of the bezil, and terminate in the girdle; under-skill facets are wrought on the pavillions, and terminate in the girdle; star-facets are wrought on the upper part of the bezil and terminate in the table.

Girdle: the line which encompasses the stone parallel to the horizon; or, which determines the greatest horizontal expansion of the stone.

Lozenges : are common to *brilliant*s and *roses*. In *brilliant*s they are formed by the meeting of the *hill* and *star-facets* on the *bezel*. In *roses* by the meeting of the facets in the horizontal ribs of the crown.

Parillons : the under sides and corners of *brilliant*s, lying between the girdle and the collet.

Ribs : the lines, or ridges, which distinguish the several parts of the work, both in *brilliant*s and *roses*.

Table : the large horizontal plane, or face, at the top of the *brilliant*.

Fig. 649 represents a *brilliant*, and fig. 650 a *rose cut diamond*.

The *rose diamond* is flat beneath, like all *wrark stones*, while the upper face rises into a dome and is cut into facets. Most usually six facets are put on the central region which are in the form of triangles, and unite at their summits ; their bases abut upon another range of triangles, which being set in an inverse position to the preceding, present their bases to them, while their summits terminate at the sharp margin of the stone. The latter triangles leave spaces between them which are likewise cut each into two facets. Ify this distribution the *rose diamond* is cut into 24 facets ; the surface of the diamond being divided into two portions, of which the upper is called the crown, and that forming the contour, beneath the former, is called *dentelle* (lace) by the French artists.

According to Mr. Jefferies, in his *Treatise on Diamonds*, the regular *rose diamond* is formed by inscribing a regular octagon in the centre of the table side of the stone, and bordering it by eight right-angled triangles, the bases of which correspond with the sides of the octagon ; beyond these is a chain of 8 trapeziums, and another of 16 triangles. The collet side also consists of a minute central octagon, from every angle of which proceeds a ray to the edge of the girdle, forming the whole surface into 8 trapeziums, each of which is again subdivided by a salient angle (whose apex touches the girdle) into one irregular pentagon and two triangles.

To fashion a rough diamond into a *brilliant*, the first step is to modify the faces of the original octahedron, so that the plane formed by the junction of the two pyramids shall be an exact square, and the axis of the crystal precisely twice the length of one of the sides of the square. The octahedron being thus rectified, a section is to be made parallel to the common base or *girdle*, so as to cut off 3 eightieths of the whole height from the upper pyramid, and 1 eightieth from the lower one. The superior and larger plane thus produced is called the *table*, and the inferior and smaller one is called the *collet* ; in this state it is termed a *complete square table diamond*. To convert it into a *brilliant*, two triangular facets are placed on each side of the table, thus changing it from a square to an octagon ; a lozenge-shaped facet is also placed at each of the four corners of the table, and another lozenge extending lengthwise along the whole of each side of the original square of the table, which with two triangular facets set on the base of each lozenge, completes the whole number of facets on the table side of the diamond ; viz. 8 lozenges, and 24 triangles. On the collet side are formed 4 irregular pentagons, alternating with as many irregular lozenges radiating from the collet as a centre, and bordered by 16 triangular facets adjoining the *girdle*. The *brilliant* being thus completed, is set with the table side uppermost, and the collet side implanted in the cavity made to receive the diamond. The *brilliant* is always three times as thick as the *rose diamond*. In France, the thickness of the *brilliant* is set off into two unequal portions ; one third is reserved for the upper part or table of the diamond, and the remaining two thirds for the lower part or collet (*culasse*). The table has eight planes, and its circumference is cut into facets, of which some are triangles and others lozenges. The collet is also cut into facets called *parillons*. It is of consequence that the *parillons* lie in the same order as the upper facets, and that they correspond to each other, so that the symmetry be perfect, for otherwise the play of the light would be false.

Although the *rose-diamond* projects bright beams of light in more extensive proportion often than the *brilliant*, yet the latter shows an incomparably greater play, from the difference of its cutting. In executing this, there are formed 32 faces of different figures, and inclined at different angles all round the table, on the upper side of the stone. On the *collet* (*culasse*) 24 other faces are made round a small table, which converts the *culasse* into a truncated pyramid. These 24 facets, like the 32 above, are differently inclined and present different figures. It is essential that the faces of the top and the bottom correspond together in sufficiently exact proportions to multiply the reflections and refractions, so as to produce the colours of the prismatic spectrum.

DIAMONDS, cutting of. Although the diamond is the hardest of all known substances, yet it may be split by a steel tool, provided a blow be applied, but this requires a perfect knowledge of the structure, because it will only yield in certain directions. This circumstance prevents the workman from forming facets or planes

generally, by the process of splitting; he is therefore obliged to resort to the process of abrasion, which is technically called *cutting*. The process of cutting is effected by fixing the diamond to be cut on the end of a stick, or handle, in a small ball of cement, that part which is to be reduced being left to project. Another diamond is also fixed in a similar manner; and the two stones being rubbed against each other with considerable force, they are mutually abraded, flat surfaces, or facets, being thereby produced. Other facets are formed by shifting the diamonds into fresh positions in the cement, and when a sufficient number are produced, they are fit for polishing. The stones, when cut, are fixed for this purpose, by imbedding them in soft solder, contained in a small copper cup, the part or facet to be polished being left to protrude.

A flat circular plate of cast-iron is then charged with the powder produced during the abrasion of the diamonds; and by this means a tool is formed which is capable of producing the exquisite lustre so much admired on a finely-polished gem. Those diamonds that are unfit for working on account of the imperfection of their lustre or colour, are sold, for various purposes, under the technical name of *Bort*. Stones of this kind are frequently broken in a steel mortar, by repeated blows, until they are reduced to a fine powder, which is used to charge metal plates of various kinds, for the use of jewellers, lapidaries, and others. *Bort*, in this state of preparation, is incapable of polishing any gems; but it is used to produce flat surfaces on rubies and other precious stones.

Fine drills are made of small splinters of *bort*, which are used for drilling small holes in rubies, and other hard stones, for the use of watch-jewellers, gold and silver wire-drawers, and others who require very fine holes drilled in such substances. These drills are also used to pierce holes in china, where rivets are to be inserted; also for piercing holes in artificial enamel teeth, or any vitreous substances, however hard.

The following description furnished to Mr. Tennant, by Messrs. Garrard, of the cutting of the Koh-i-noor will fully explain the peculiar conditions of the process, and also show that there are some remarkable differences in the physical condition of the gem in its different planes. The letters refer to the cut of the Koh-i-noor, article DIAMOND, fig. 644.

"In cutting diamonds from the rough, the process is so uncertain that the cutters think themselves fortunate in retaining one-half the original weight. The Koh-i-noor, on its arrival in England, was merely surface cut, no attempt having been made to produce the regular form of a brilliant by which alone lustre is obtained. My reference to the figures, which are the exact size of the Koh-i-noor, it will be clearly understood that it was necessary to remove a large portion of the stone in order to obtain the desired effect, by which means the apparent surface was increased rather than diminished, and the flaws and yellow tinge were removed.

"The process of diamond cutting is effected by an horizontal iron plate of about ten inches diameter, called a *schyf*, or *mill* which revolves from two thousand to three thousand times per minute. The diamond is fixed in a ball of pewter at the end of an axis, resting upon the table in which the plate revolves; the other end, at which the ball containing the diamond is fixed, is pressed upon the wheel by movable weights at the discretion of the workmen. The weight applied varies from 2 to 30 lbs. according to the size of the facets intended to be cut. The recutting of the Koh-i-noor was commenced on July 16, 1852, His Grace the late Duke of Wellington being the first person to place it on the mill; the portion first worked upon was that at which the planes *r* and *s* meet, as it was necessary to reduce the stone at that part, and so to level the rest of the stone before the table could be formed; the intention being to turn the stone rather on one side, and take the incision or flaw at *a*, and a fracture on the other side of the stone, not shown in the engraving, as the boundaries or sides of the girdle. The next important step was the attempt to remove an incision or flaw at *c*, described by Professor Tennant and the Rev. W. Mitchell as having been made for the purpose of holding the stone more firmly in its setting, but pronounced by the cutters (after having cut into and examined it) to be a natural flaw of a yellow tinge, a defect often met with in small stones. The next step was cutting a facet on the top of the stone immediately above the last mentioned flaw. Here the difference in the hardness of the stone first manifested itself; for while cutting this facet, the lapidary noticing that the work did not proceed so fast as hitherto, allowed the diamond to remain on the mill rather longer than usual, without taking it off to cool; the consequence was, that the diamond became so hot from the continual friction and greater weight applied, that it melted the pewter in which it was imbedded. Again, while cutting the same facet, the mill became so hot from the extreme hardness of the stone, that particles of iron mixed with diamond powder and oil ignited. The probable cause of the diamond proving so hard at this part is, that the lapidary was obliged to cut directly upon the angle at which two cleavage planes meet, cutting across the grain of the stone. Another step that was then considered to

be important by the cutters was removing a flaw at *a*. This flaw was not thought by Professor Tennant and Mr. Mitchell to be dangerous, because if it were allowed to run according to the cleavage, it would only take off a small piece, which it was necessary to remove in order to acquire the present shape. The cutters, however, had an idea that it might not take the desired direction, and, therefore, began to cut into it from both sides, and afterwards directly upon it, and thus they succeeded in getting rid of it. While cutting, the stone appeared to become harder and harder the further it was cut into, especially just above the flaw at *a*, which part became so hard, that, after working the mill at the medium rate of 2400 times per minute, for six hours, little impression had been made; the speed was therefore increased to more than 3000, at which rate the work gradually proceeded. When the back (or former top) of the stone was cut, it proved to be much softer, so that a facet was made in three hours, which would have occupied more than a day, if the hardness had been equal to that on the other side; nevertheless, the stone afterwards became gradually harder, especially underneath the flaw at *a*, which part was nearly as hard as that directly above it. The flaw at *a* did not interfere at all with the cutting. An attempt was made to cut out the flaw at *a*, but it was found not desirable on account of its length. The diamond was finished on September 7th, having taken thirty-eight days to cut, working twelve hours per day without cessation." The weight of the Koh-i-Noor since cutting is 102½ carats.

DIAMOND DUST. The use of diamond dust within a few years has increased very materially, on account of the increased demand for all articles that are wrought by it, such as cutters, intaglios, &c. There has been a discovery made of the peculiar power of diamond dust upon steel; it gives the finest edge to all kinds of cutlery, and it threatened at one time to displace the hone of Hungary. Finely powdered corundum, however, now occupies its place. It is well known that in cutting a diamond, the dust is placed on the teeth of the saw—to which it adheres; to this dust is to be attributed solely the power of man to make brilliants from rough diamonds. The dust enables the polisher to obtain the perfection of geometrical symmetry, which is one of the chief beauties of the mineral, and also that adamantine polish, which nothing can injure or affect, save a substance of its own nature.

Diamond dust, it would appear, can now be manufactured by the agency of voltaic electricity. See **DIAMOND**.

DIAMOND MICROSCOPES were first suggested by Dr. Goring, and have been well executed by Mr. Pritchard. Previous to grinding a diamond into a spherical figure, it should be ground flat and parallel upon both sides, that by looking through it, as opticians try flint glass, we may see whether it has a double or triple refractive power, as many have, which would render it useless as a lens. Among the different crystalline forms of the diamond, probably the octahedron and the cube are the only ones that will give a single vision. It will, in many cases, be advisable to grind diamond lenses plano-convex, both because this figure gives a low spherical aberration, and because it saves the trouble of grinding one side of the gem. A concave tool of cast iron, paved with diamond powder, hammered into it by a hardened steel punch, was employed by Mr. Pritchard. This ingenious artist succeeded in computing a double convex of equal radii, of about $\frac{1}{4}$ of an inch focus, bearing an aperture of $\frac{1}{8}$ of an inch with distinctness upon opaque objects, and its entire diameter upon transparent ones. This lens gives vision with a trifling chromatic aberration; in other respects, like Dr. Goring's American reflector, but without its darkness, its light is said to be superior to that of any compound microscope whatever, acting with the same power, and the same angle of aperture. The advantage of seeing an object without aberration by the interposition of only a single magnifier, instead of looking at a picture of it with an eye-glass, is evident. We thus have a simple direct view, whereby we shall see more accurately and minutely the real texture of objects.

DIAMOND TOOLS. 1. *The Glazier's diamond* is the natural diamond, so set that one of its edges is brought to bear on the glass.

The extreme point of any diamond will scratch glass, making a white streak; but when the rounded edge of a diamond is slid over a sheet of glass with but slight pressure, it produces a cut, which is scarcely visible, but which readily extends through the mass.

Dr. Wollaston succeeded in giving to the ruby, topaz, and rock crystal forms similar to those of the diamond, and with these he succeeded in cutting glass; proving that the useful property of the diamond depended on its form. Although the primitive form of the diamond is that of a regular octahedron, the Duke de Bourbon has published upwards of one hundred forms of crystallization of the diamond. The irregular octahedrons with round facets are those proper for glaziers' diamonds.

Notwithstanding the hardness of the diamond, yet, in large glass works, as many as one and two dozens are worn out every week; from being convex, they become rapidly concave, and the cutting power is lost.

2. *Diamond drills* are made of various shapes; these are either found amongst imperfect diamonds, or, are selected from fragments split off from good-stones in their manufacture for jewellery.

DIAPER is the name of a kind of cloth, used chiefly for table linen. It is known among the French by the name of *toile fourré*, and is ornamented with the most extensive figures of any kind of tweeled cloth, excepting damask. The mounting of a loom for working diaper is, in principle, much the same as a draw-loom, but the figures being less extensive, the mounting is more simple, and is wrought entirely by the weaver, without the aid of any other person. As tweeled cloths, of any number of leaves, are only interwoven at those intervals when one of the leaves is raised, the wool above and the warp below are kept floating or flushed, until the intersection takes place. Of consequence the floating yarn above appears across the fabric, and that below longitudinally. This property of tweeled cloths is applied to form the ornamental figures of all kinds of tweeled goods, merely by reversing the floating yarn when necessary. In the sampler pattern, this is effected by a few additional leaves of treddles; but when the range of pattern becomes too great to render this convenient, an apparatus called a *back harness* is employed, and the cloth woven with this mounting is called diaper. Diapers are generally five-leaf tweels, that is to say, every warp floats under four threads of wool, and is raised, and of course interwoven with the fifth. This is done either successively, forming diagonals at 45° upon the cloth, or by intervals of two threads, which is called the broken tweel. The latter is generally, if not universally, adopted in the manufacture of diaper. The reason of preferring the broken to the regular tweel, where ornaments are to be formed, is very obvious. The whole depending upon reversed flushing, to give the appearance of oblique or diagonal lines through either, would destroy much of the effect, and materially injure the beauty of the fabric. The broken tweel, on the contrary, restores to the tweeled cloth a great similarity of appearance to plain or alternately interwoven fabrics, and at the same time preserves the facility of producing ornaments by reversing the flushing.

DIASTASE. A white and tasteless substance, obtained by moistening pounded malt, and squeezing the water through a bag. Albumen is precipitated from the turbid fluid by alcohol, and filtered. Then the diastase is precipitated by an additional quantity of alcohol, and purified by re-solution and re-precipitation. One part of diastase will convert 2000 parts of starch into dextrine, and 1000 parts into sugar.

DICHROISM. The property of exhibiting two colours. Many of the phenomena belong to the conditions producing **FLUORESCENCE**, which see. Some of the phenomena have been referred to polarisation, but this requires examination.

DIDYMIUM (Di). A metal discovered by Mosander, in 1841, in *oxide of cerium*, and so called as being associated in that ore as a twin brother with *lanthanum*.

The oxide of Didymium (DiO) is a dark brown powder; the salts are pink, or rose, and amethyst or violet.

DIES FOR STAMPING. (*Coin*, Fr.; *Münzstampeln*, Germ.) The first circumstance that claims particular attention in the manufacture of dies, is the selection of the best kind of steel for the purpose, and this must in some measure be left to the experience of the die-forgers, who, if well skilled in his art, will be able to form a tolerably correct judgment of the fitness of the metal for the purpose, by the manner in which it works upon the anvil. It should be rather fine-grained than otherwise, and above all things perfectly even and uniform in its texture, and free from spots and patches finer or coarser than the general mass. But the very fine and uniform steel with a silky fracture, which is so much esteemed for some of the purposes of cutlery, is unfit for our present purpose, from the extreme facility with which it acquires great hardness by pressure, and its liability to cracks and flaws. The very coarse-grained, or highly crystalline steel, is also equally objectionable; it acquires fissures under the die-press, and seldom admits of being equally and properly hardened. The object, therefore, is to select a steel of a medium quality as to fineness of texture, not easily acted upon by dilute sulphuric acid, and exhibiting an uniform texture when its surface is washed over with a little aquafortis, by which its freedom from pins of iron, and other irregularities of composition, is sufficiently indicated.

The best kind of steel being thus selected, and properly forged at a high heat into the rough die, it is softened by very careful annealing, and in that state, having been smoothed externally, and brought to a table in the turning lathe, it is delivered to the engraver.

The process of annealing the die consists in heating it to a bright cherry red, and suffering it to cool gradually, which is best effected by holding it in a crucible or iron pot of coarsely-powdered charcoal. In this operation it is sometimes supposed that the die, or at least its superficial parts, becomes super-carbonised, or highly converted steel, as it is sometimes called; but experience does not justify such an opinion, and I believe the composition of the die is scarcely, certainly not

materially, affected by the process, for it does not remain long enough in the fire for the purpose.

The engraver usually commences his labours by working out the device with small steel tools in intaglio; he rapidly begins in relief (though this is sometimes done); and having ultimately completed his design, and satisfied himself of its general effect and correctness, by impressions in clay, and dabs, or casts in type metal, the die is ready for the important operation of hardening, which, from various causes, a few of which I shall enumerate, is a process of much risk and difficulty; for should any accident now occur, the labour of many months may be seriously injured, or even rendered quite useless.

The process of hardening soft steel is in itself very simple, though not very easily explained upon mechanical or chemical principles. We know by experience, that it is a property of this highly valuable substance to become excessively hard, if heated and suddenly cooled; if, therefore, we heat a bar of soft malleable and ductile steel red hot, and then suddenly quench it in a large quantity of cold water, it not only becomes hard, but fragile and brittle. But as a die is a mass of steel of considerable dimensions, this hardening is an operation attended by many and peculiar difficulties, more especially as we have at the same time to attend to the careful preservation of the engraving. This is effected by covering the engraved face of the die with a protecting face, composed of fixed oil of any kind, thickened with animal charcoal; some persons add pipe-clay, others use a pulp of garlic, but pure lamp-black and linseed oil answer the purpose perfectly. This is thinly spread upon the work of the die, which, if requisite, may be further defended by an iron ring; the die is then placed with its face downwards in a crucible, and completely surrounded by animal charcoal. It is heated to a suitable temperature, that is, about cherry red, and in that state is taken out with proper tongs, and plunged into a body of cold water, of such magnitude as not to become materially increased in temperature; here it is rapidly moved about, until all noise ceases, and then left in the water till quite cool. In this process it should produce a bubbling and hissing noise; if it pipes and sings, we may generally apprehend a crack or fissure.

No process has been found to answer better than the above simple and common mode of hardening dies, though others have had repeated and fair trials. It has been proposed to keep up currents and eddies of cold water in the hardening cistern, by means of delivery pipes, coming from a height; and to subject the hot die, with its face uppermost, to a sudden and copious current of water, let fall upon it from a large pipe, supplied from a high reservoir; but these means have not in any way proved more successful, either in saving the die, or in giving it any good qualities. It will be recollected, from the form of the die, that it is necessarily only, as it were, case-hardened, the hardest strata being outside, and the softer ones within, which envelope a core, something in the manner of the successive coats of an onion; an arrangement which we sometimes have an opportunity of seeing displayed in dies which have been smashed by a violent blow.

The hardening having been effected, and the die being for the time safe, some further steps may be taken for its protection; one of these consists in a very mild kind of tempering, produced by putting it into water, gradually raised to the boiling point, till heated throughout, and then suffering it gradually to cool. This operation renders the die less apt to crack in very cold weather. A great safeguard is also obtained by thrusting the cold die into a red-hot iron ring, which just fits it in that state, and which, by contracting as it cools, keeps its parts together under considerable pressure, preventing the spreading of external cracks and fissures, and often enabling us to employ a split or die for obtaining punches, which would break to pieces without the protecting ring.

If the die has been successfully hardened, and the protecting paste has done its duty by preserving the face from all injury and oxidisement, or burning, as it is usually called, it is now to be cleaned and polished, and in this state constitutes what is technically called a *MATRIX*; it may of course be used as a multiplier of medals, coins, or impressions, but it is not generally thus employed, for fear of accidents happening to it in the coming press, and because the artist has seldom perfected his work upon it in this state. It is, therefore, resorted to for the purpose of furnishing a burn, or steel impression for relief. For this purpose a proper block of steel is selected, of the same quality, and with the same precautions as before, and being carefully annealed, or softened, is turned like the matrix, perfectly true and flat at the bottom, and obtusely conical at top. In this state, its conical surface is carefully compressed by powerful and proper machinery upon the matrix, which, being very hard, soon allows it to receive the commencement of an impression; but in thus receiving the impression, it becomes itself so hard by condensation of texture, as to require during the operation to be repeatedly annealed, or softened, otherwise it would split into small

superficial fissures, or would injure the matrix; much practical skill is therefore required in taking the impression, and the punch, at each annealing, must be carefully protected, so that the work may not be injured.

Thus, after repeated blows in the die-press, and frequent annealing, the impression from the matrix is at length perfected, or brought completely up, and having been retouched by the engraver, is turned, hardened, and collared, like the matrix, of which it is now a complete impression in relief, and, as we have before said, is called a punch.

The punch becomes an inexhaustible parent of dies, without further reference to the original matrix; for now by impressing upon it plugs of soft steel, and by paring with them an exactly similar operation to that by which the punch itself was obtained, we procure impressions from it to any amount, which, of course are fac-similes of the matrix, and these dies being turned, hardened, polished, and, if necessary, tempered, are employed for the purposes of coinage.

The distinction between striking medals and common coin is very essential, and the work upon the dies is accordingly adjusted to each. Medals are usually in very high relief, and the effect is produced by a succession of blows; and as the metal in which they are struck, be it gold, silver, or copper, acquires considerable hardness at each stroke of the press, they are repeatedly annealed during the process of bringing them up. In a beautiful medal, which Mr. Wyon executed for the Royal Naval College, the obverse represents the head of the King, in very bold relief; it required thirty blows of a very powerful press to complete the impression, and it was necessary to anneal each medal after every third blow, so that they went ten times into the fire for that purpose. In striking a coin or medal, the lateral spread of the metal, which otherwise would ooze out as it were from between the dies, is prevented by the application of a steel collar, accurately turned to the dimensions of the dies, and which, when left plain, gives to the edge of the piece a finished and polished appearance; it is sometimes grooved, or milled, or otherwise ornamented, and occasionally lettered, in which case it is made in three separate and movable pieces, confined by a ring, into which they are most accurately fitted, and so adjusted that the metal may be forced into the letters by its lateral spread, at the same time that the coin receives the blow of the screw press.

Coins are generally completed by one blow of the coining-press. These presses are worked in the Royal Mint by machinery, so contrived that they shall strike, upon an average, sixty blows in a minute; the blank piece, previously properly prepared and annealed, being placed between the dies by part of the same mechanism.

The number of pieces which may be struck by a pair of dies of good steel, properly hardened and duly tempered, not infrequently amounts at the Mint to between one and two hundred thousand; but the average consumption of dies is of course much greater, owing to the variable qualities of steel, and to the casualties to which the dies are liable; thus, the upper and lower die are sometimes struck together, owing to an error in the layer-on, or in that part of the machinery which ought to put the blank into its place, but which now and then fails so to do. This accident very commonly arises from the boy who superintends the press neglecting to feed the hopper of the layer-on with blank pieces. If a die is too hard, it is apt to break or split, and is especially subject to fissures, which run from letter to letter upon the edge. If too soft, it swells, and the collar will not rise and fall upon it, or it sinks in the centre, and the work becomes distorted and faulty. He, therefore, who supplies the dies for an extensive coinage, has many accidents and difficulties to encounter. There are eight presses at the Mint, frequently at work for ten hours each day, and the destruction of eight pair of dies per day (one pair for each press) may be considered a fair average result, though they much more frequently fall short of, than exceed this proportion. It must be remembered, that each press produces 3600 pieces per hour; but making allowance for occasional stoppages, we may reckon the daily produce of each press at 30,000 pieces; the eight presses, therefore, will furnish a diurnal average of 240,000 pieces.

DIES, hardening of. See **STEEL, hardening of.**

DIGESTER is the name of a copper kettle or pot of small dimensions, made very strong, and mounted with a safety valve in its top. Papin, the contriver of this apparatus, used it for subjecting bones, cartilages, &c. to the solvent action of high-pressure steam, or highly heated water, whereby he proposed to facilitate their digestion in the stomach. This contrivance is the origin of the French cookery pans, called *autoclaves*, because the lid is self-keyed, or becomes steam-tight: by turning it round under clamps or ears at the sides, having been previously ground with emery to fit the edge of the pot exactly. In some autoclaves the lid is merely laid on with a sheet of linen as a lute, and then secured in its place by means of a screw bearing down upon its centre from an arched bar above. The safety valve is loaded either by a weight placed vertically upon it, or by a lever of the second kind pressing near its fulcrum.

and acted upon by a weight which may be made to bear upon any point of its graduated arm.

Chevreul has made a useful application of the digester to vegetable analysis. His instrument consists of a strong copper cylinder, into which enters a tight cylinder of silver, having its edge turned over at right angles to the axis of the cylinder, so as to form the rim of the digester. A segment of a copper sphere, also lined with silver, stops the aperture of the silver cylinder, being applied closely to its rim. It has a conical valve pressed with a spiral spring, of any desired force, estimated by a steel-yard. This spring is enclosed within a brass box perforated with four holes, which may be screwed into a tapped orifice in the top of the digester. A tube screwed into another hole serves to conduct away the condensable vapours at pleasure into a Woulfe's apparatus.

DIKE or DYKE. A wall like division in rocks, produced by the ejection of trapezoidal matter in a fused state from below, through the overlying strata. In many places these hard trap rocks stand out above the adjacent rocks, which have been worn away, presenting actually the appearance of a massive wall.

DILATATION. The increase of size produced in bodies by the agency of heat. See **EXPANSION**.

DILUVIUM. (*Diluvium*.) Deluge. Those accumulations of gravel and loose materials, which, by some geologists, are said to have been produced by the action of a diluvial wave or deluge, sweeping over the surface of the earth.—*Lyell*.

DIMITY is a kind of cloth cotton originally imported from India, and now manufactured in great quantities in various parts of Britain, especially in Lancashire. Dr. Johnson calls it *dimity*, and describes it as a kind of fustian. The distinction between fustian and dimity seems to be, that the former designates a common towed cotton cloth of a stout fabric, which receives no ornament in the loom, but is most frequently dyed after being woven. Dimity is also a stout cotton cloth, but not usually of so thick a texture; and is ornamented in the loom, either with raised stripes or fancy figures: it is seldom dyed, but usually employed white, as for bed and bed-room furniture. The striped dimities are the most common, they require less labour in weaving than the others; and the mounting of the loom being more simple, and consequently less expensive, they can be sold at much lower rates.

DIOPTRIC LIGHTHOUSES. See **LIGHTHOUSES**.

DIORITES. A trap or granitic rock, in which *albite* replaces *orthoclase*. Diorites are abundant in the *Voages*.

DIP. When any stratum, mineral vein, or dike, does not lie horizontally it is said to dip E. W. N. or S., as the case may be. The angle which it makes with the horizon is called the angle of the dip.

DUPPEL'S ANIMAL OIL. A fetid volatile oil obtained when animal substances, such as bone, are subjected to distillation. That which is found in commerce is obtained in the manufacture of bone-black.

DIPPING. Ornamental works in brass are usually brightened by a process called *dipping*. After the work has been properly fitted together and the gross ground, either by the action of heat, or by boiling in a pearl ash lye, it is *pickled* in a bath of dilute aqua fortis. It is then scoured bright with sand and water, and being well washed is plunged into the dipping bath, which consists of pure nitrous acid, commonly known as *dipping aqua fortis*, for an instant only, and is then well washed with cold and hot water to remove every trace of acid from the surface, after which the work is put into dry beech or box wood, sawdust, &c., well rubbed until it is quite dry, and then burnished and lacquered with as little delay as possible.

DISINFECTANT. A substance which removes the putrid or infected condition of bodies. It is well not to confound it with antiseptic, which applies to those bodies which prevent putrefaction. The word disinfectant has lately become somewhat uncertain in its meaning, on account of a word being used as its equivalent, viz. deodoriser. This latter means a substance which removes odours. In reality, however, there are no such substances known to us as a class. There are, of course, some substances which destroy certain others having an odour, but in all cases the removal of the smell and the destruction or neutralisation of the body must be simultaneous. There is, however, a large class of substances that destroy putrefaction, and the name disinfectant is therefore distinctly needed. The gases which rise from putrefying bodies are not all capable of being perceived by the nose in their ordinary condition, but sometimes they are perceived. A disinfectant puts a stop to them and deodorises simultaneously. If a substance were to remove the smell of these gases, it would remove the gases too, as they are inseparable from their property of affecting the nose. A deodoriser would therefore be, and is, a disinfectant of that gas the smell of which it removes. But it has been proposed that it may remove those gases which smell, and allow the most deleterious to pass, they having no smell. Whenever we find such a substance, it will be well to give them

the name of deodorisers. There may be some truth in the hypothesis that metallic salts remove the sulphur, and by preventing the escape of sulphuretted hydrogen cause less odour, without complete disinfection. But it appears that the decomposition is a prevention of putrefaction in proportion to the removal of that gas in cases where it is given out, and it is quite certain that metallic solutions have disinfecting properties. Any solution having the effect here supposed would at the least be a partial disinfectant, inasmuch as the decomposition would be so far put a stop to, as to prevent at least one obnoxious gas. How the others could remain unacted on in this case it is difficult to comprehend. To prevent the formation of one gas is to arrest decomposition or to alter the whole character of the change which is producing the gases. The most deleterious of emanations have no smell at all to the ordinary senses, and we can only judge of the evil by its results, or the fact that the substances capable of producing it are near, or by the analysis of the air. (See SANITARY ARRANGEMENTS.) The cases where sulphuretted hydrogen accompanies the offensive matter, are chiefly connected with faecal decomposition. This gas is a useful indication of the presence of other substances. So far as is known, the destruction of the one causes the destruction of the other. But the presence of sulphuretted hydrogen is no proof of the presence of infectious matter, nor is its absence a proof of the absence of infectious matter, it being only an occasional accompaniment. When the infectious matter and the odoriferous matter are one, as in the case, as far as we know, of putrid flesh, &c., then to decolorise is to disinfect. We can find then no line of duty to be performed by deodorisers, and no class of bodies that can bear the name, although there may be a few cases where the word may be found convenient. If, for example, we destroy one smell by superadding a greater, that might in one sense be a deodorising. If we added an acid metallic salt, and removed the sulphuretted hydrogen, letting loose those organic vapours which for awhile accompany this act, we might, to those who were not very near, completely destroy smell, and still send a substance into the air by no means wholesome; but in such a case decomposition is stopped, at least for a while. The smelling stage is by no means the most dangerous, nor has the use of the word *deodorise* any relation to sanitary matters, except in the grossest sense; it is desirable that persons should look far beyond the mere indications furnished by the nose, and as in science we can find no deodorisers, so in practice we need not look for any in the sense usually given to the word. The word may be used for such substances as remove the odour and the putrefaction of the moment, but allow them to begin again. Even in this case deodorisers become temporary disinfectants, which character all removers of smell must more or less have.

Antisepsis, or colytic agents. Substances which prevent decomposition. The words *colysis* and *colytic* come from *καλύω*, to arrest, restrain, cut short. This word was proposed by the writer to apply to cases such as are included under antiseptics, antiferments, and similar words. There was needed a word for the general idea. A colytic force manifests itself towards living persons in anæsthetics, anodynes, and narcotics, as well probably, as in other ways. Colytics may probably act from different causes, but these causes not being separately distinguished, a name for the whole class can alone be given. The action of *colysis* is entirely opposed to *catalysis*, which is a loosening up of a compound. *Colysis* arrests *catalysis*, as well also as other processes of decomposition, ordinary oxidation for example. Disinfectants in their character of restraining further decomposition, are included under *colytics*. One of the most remarkable substances for arresting decomposition is kresote. It has been used in some condition or mixture from the earliest times. The ancient oil of cedar has been called with good reason turpentine, which has strong disinfecting properties, but the word has evidently been used in many senses, as there are many liquids to be obtained from cedar. It is used for the first liquid from the distillation of wood; and Herzelius for that reason says that the Egyptians used the pyroligneous acid, which, containing some kresote, was a great antiseptic. But a mixture of this acid with soda would be of little value in embalming, nor is it probable that they would add a volatile liquid like turpentine along with caustic soda. It is expressly said (in Pliny) that the pitch was reboiled, or, in other words, the tar was boiled and distilled, the product being collected in the wool of fleeces, from which again it was removed by pressure. In doing this the light oils or naphtha would be evaporated, and the heavy oil of tar, containing the carbolic acid, or kresote, would remain. It was called *piceum*, as if made of pitch or pissinum, and pissinum or pitch oil, a more appropriate name than that of Runge's carbolic acid or coal-oil, and still more appropriate than the most recent, which, by following up a theory, has converted it into phenic acid. The distillation was made in copper vessels, and must have been carried very far, as they obtained "a reddish pitch, very clammy, and much fatter than other pitch." This was the *anthracene*, *chrysene*, and *pyrene* of modern chemistry. The remaining hard pitch was called *palumpissa*, or second pitch, which we call pitch in contradistinction

to tar. By the second pitch, however, was sometimes meant the product of distillation instead of what was left in the still. Some confusion therefore exists in the names, but not more than with us. The pitch oil was resinous fat, and of yellow colour, according to some. This oil containing kresote, was used for toothache—a colytic action applied to living bodies—and for skin diseases of cattle, for which it is found valuable. They also used it for preserving hams.—(*"Disinfectants,"* by the Writer. *Jour. Soc. of Arts*, 1857.)

It is quite possible that kresote may be the chief agent in most empyreumatic substances which act as antiseptics. But it is not the only agent. Hydrocarbons of various kinds act as antiseptics, as well as alcohol and methylic alcohol, which contain little oxygen. To this class belong essential oils and substances termed perfumes, which are used for fumigation, and have also a powerful colytic action. It is exceedingly probable that the true theory of this action is connected with the want of oxygen. These substances do not rapidly oxidise, but, on the contrary, only very slowly, and that chiefly by the aid of other bodies. Their atoms are, therefore, in a state of tension, ready to unite when assisted. As an example, carbolic acid and kresote unite with oxygen when a base is present, and form rosolic acid. We can scarcely suppose that an explanation, commonly resorted to in the case of sulphurous acid, would suit them; viz., that it takes up the oxygen, and so keeps it from the putrescible substance. It is, therefore, much more likely that its condition acts on the putrescible body. For, as the state of motion of a putrefying substance is transferred to another, so is the state of immobility.

In 1750 Sir John Pringle wrote his "*Experiments on Septic and Antiseptic Substances*, with remarks relating to their Use in the Theory of Medicine." He recommended salts of various kinds, and astringent and gummy parts of vegetables and fermenting liquors. Dr. Macbride followed him with numerous experiments. He speaks of acids being the long prescribed agents as antiseptics. He found them antiseptic even when diluted to a great extent. Alkalies also he found antiseptic, and salts in general. Also "gum-resins, such as myrrh, assafetida, aloes, and terra japonica," besides "decoctions of Virginia snake-root, pepper, ginger, saffron, contrayerva root, sage, valerian root, and rhubarb, with mint, angelica, senna, and common wormwood." Many of the common vegetables also were included as to some extent antiseptic; such as horse-radish, mustard, carrots, turnips, garlic, onions, celery, cabbage, colewort. Lime was found to prevent, but not to remove putrefaction. We are inclined at present very much to qualify some of these observations. Animal fluids, he observes, will remain for a long time without putridity if kept from the air. He says that astringent mineral acids and ardent spirits "not only absorb the matter from the putrescent substances, but likewise crisp up its fibres, and thereby render it so hard and durable that no change of combination will take place for many years." He adds also molasses to the antiseptics. In 1767 the academy of Dijon gave a prize for the use of nitrate of potash in ventilation. This may have given the first idea to Carmichael Smyth. Guyton-Morveau came later with a volume of valuable experiments on acids.

An antiseptic preserves from putrefaction, but does not necessarily remove the odour caused by that which has previously putrefied. Many of the substances described as disinfectants here, might equally be called antiseptics. When they remove the putrid matter they are disinfectants, when they prevent decomposition they are antiseptics. But when the smell is removed by a substance which is known to destroy putrefactive decomposition, and to preserve organic matter entire, then we have the most thorough disinfection; then we know that the removal of the smell is merely an indication of the removal of the evil.

Disinfectants are of various kinds. Nature seems to use soil as one of the most active. All the dejects of the animals on the surface of the earth fall on the soil, and are rapidly made perfectly innocuous. Absorption distinguishes porous bodies, and the soil has peculiar facilities for the purpose. But if saturated, it could disinfect no longer. This is not allowed to occur; the soil absorbs air also, and oxidises the organic matter which it has received into its pores, and the offensive matter is by this means either converted into food for plants, or is made an innocent ingredient of the air, or, if the weather be moist, of the water. The air is therefore, in conjunction with the soil, one of the greatest disinfectants, but it acts also quite alone and independent of the soil. Its power of oxidising must be very great. The amount of organic effluvia sent into large towns is remarkable, and yet it seldom accumulates so as to be strongly perceptible to the senses. The air oxidises it almost as rapidly as it rises; this is hastened apparently by the peculiar agent in the air, ozone, which has a greater capacity of oxidation than the common air; when this is exhausted it is highly probable that the oxidation will be much slower, and this exhaustion does take place in a very short time. So rapid is the oxidation, that the wind, even

blowing at the rate of about fifteen to twenty miles an hour, is entirely deprived of its ozone by passing over less than a mile of Manchester. In London this does not take place so rapidly, at least near the Thames. But when the ozone is removed, it is probable that the rate of increase of the organic matter will be much greater. We may by this means, then, readily gauge the condition of a town up to a certain point by the removal of the ozone; but it requires another agent to gauge it afterwards, or thoroughly. It is in connection with each other that the air and the soil best disinfect. When manure is thrown upon land without mixing with the soil, it may require a very long period to obtain thorough disinfection, but when the atmosphere is moist, or rain falls, then the air is rapidly transferred into every portion of the porous earth, and the organic matter becomes rapidly oxidised. To prevent a smell of manure, and with it also the loss of ammonia, it is then needful that as soon as possible the manure should be mixed with the soil. The same power of oxidation is common to all porous bodies, to charcoal, and especially, as Dr. Stenhouse has shown, to platinised charcoal. Disinfection by the use of porous bodies is not a process of preservation, but of slow destruction. It is an oxidation in which all the escaping gases are so thoroughly oxidised, that none of them have any smell or any offensive property. But being so, the body disinfected must necessarily decay, and in reality the process of decay is remarkably increased. All such bodies must therefore be avoided when manures are to be disinfected, as the valuable ingredients are destroyed instead of being preserved. Stenhouse has employed charcoal for disinfecting the air. The air is passed through the charcoal either on a large scale for a hospital or on a small scale as a respirator for the mouth. Care must be taken, however, to keep the charcoal dry: wet charcoal is not capable of absorbing air until that air is dissolved in the water. This solution takes place less rapidly in water. Wet charcoal is therefore a filter for fluids chiefly, and dry charcoal for vapours. Its destructive action on manures will, however, always prevent charcoal from being much used as a disinfectant for such purposes, or, indeed, any other substance which acts principally by its porosity or by oxidation. This the soil does only partially, as it has another power, viz. that of retaining organic substances fit to be the food of plants. Although air acts partly in conjunction with the soil and the rain to cause disinfection, and partly by its own power, it also acts mechanically as a means of removing all noxious vapours. The wind and other currents of the air are continually ventilating the ground, and when these movements are not sufficiently rapid, or when they are interrupted by our mode of building, we are compelled to cause them artificially, and thus we arrive at the art of ventilation. The addition of one tenth of a per cent. of carbonic acid to the air may be perceived, at least if accompanied with the amount of organic matter usually given out at the same time in the breath, and as we exhale in a day 20 cubic feet of carbonic acid, we can injure the quality of 20,000 cubic feet of air in that time. The great value of a constant change of air is therefore readily proved, and the instinctive love which we have of fresh air is a sufficient corroboration.

Cold is a great natural disinfectant. The flesh of animals may be preserved as far as we know for thousands of years in ice; purifying emanations are completely arrested by freezing, but the mobility of the particles, or chemical action, is also retarded by a degree of cold much less than freezing.

Heat is also a disinfectant, when it rises to about 140° of Fahrenheit, according to Dr. Henry. But as a means of producing dryness it is a disinfectant at various temperatures. Nothing which is perfectly dry can undergo putrefaction. On the other hand heat with moisture below 140° is a condition very highly productive of decomposition and all its resulting evils. Disinfection by heat is used at quarantine stations. Light is undoubtedly a great disinfectant; so far as we know, it acts by hastening chemical decomposition. In all cases of ventilation, it is essential to allow the rays of light to enter with the currents of air. Its effect on the vitality of the human being is abundantly proved, and is continually asserting itself in vegetation. The true disinfecting property of light exists in all probability in the chemical rays which cause compositions and decompositions. Water, however, is of all natural disinfectants the most manageable, and there is no one capable of taking its place actively. Wherever animals even human beings, live, there are emanations of organic matter, even from the pores. The whole surface of the house, furniture, floor, and walls, becomes coated by degrees with a thin covering, and this gradually decomposes, and gives off unpleasant vapours. Sometimes it becomes planted with fungi, and so seeds plants of this kind. Not long before this occurs a small amount of vapour is given off sufficiently disagreeable to affect the senses, and sometimes affecting the spirits and the health before the senses distinctly perceive it. This must be removed. In most cases this film is removed by water, and we have the ordinary result of household cleanliness; but in other cases when the furniture is such as will be injured by water, the removal is made by friction or by oil or turpentine, and other substances used to polish. Water as a disinfectant

is used also in washing of clothes, for this purpose nothing whatever can supply its place, although it requires the assistance both of soap and friction, or agitation and heat. Water is also used as a mechanical agent for removing filth, and the method which Hercules devised of using a river to wash away filth, is now adopted in all the most advanced plans of cleansing towns. It is only by means of water that the refuse of towns can be conveyed away in covered and impervious passages, whilst none whatever is allowed to remain in the town itself. In cases where this cannot be done, it is much to be desired that some disinfecting agent should be used to prevent decomposition. Where water is not used, as in water-closets, there must of course be a great amount of matter stored up in middens, and the town is of course continually exposed to the effluvia. Besides these methods of acting, water disinfects partly by preventing effluvia from arising from bodies, simply because it keeps them in solution. This action is not a perfect one, but one of great value. The water gives off the impurity slowly, sometimes so slowly as to be of no injury, or it keeps it so long that complete oxidation takes place. The oxygen for this purpose is supplied by the air, which the water absorbs without ceasing. To act in this way, water must be delivered in abundance; when only existing as a moisture, water may act as a great opponent to disinfection by rising up in vapour loaded with the products of decomposition.

Mere drying is known to arrest decay, as the mobility of the particles in decomposition is stayed by the want of water. We are told in Andersson's travels in S. Africa, that the Damaras cut their meat into strips, and dry it in the sun, by which means it is preserved fresh. A similar custom is found in S. America. Certain dews prevent this, and decomposition sets in rapidly. A little overclouding of the sky, or a little more moisture in the air, quickly stops the process.

The above may be called natural disinfectants, or imitations of natural processes, charcoal being introduced as an example of a more decided character of porous action. They show both mechanical and chemical action. The mechanical, when water or air removes, dilutes, or covers the septic bodies; the chemical, when porous bodies act as conveyers of oxygen; or an union of both, when cold and heat prevent the mobility of the particles. The action by oxidation causes a destruction of the offensive material. The other method is antiseptic. It is much to be desired that all impurities should be got rid of by some of these methods, but especially by the air, the water, and the soil. There are, however, conditions in which difficulties interfere with the action. Large towns may be purified by water, but what is to be done with the water which contains all the impurity? If put upon land, it is very soon disinfected, but on its way to the land it may do much mischief. It has been proposed to disinfect it on its passage, and even in the sewers themselves; by this means the town itself is freed from the nuisance, and the water may be used where it is needed without fear. This introduces artificial disinfectants. There are other cases where such are required; when the refuse matter of a town is allowed to lie either in exposed or in underground receptacles; in this case a town is exposed to an immense surface of impurity, and disinfectants would greatly diminish the evil, if not entirely remove it. There are besides, special cases without end continually occurring, where impurities cannot be at once removed, and where treatment with artificial disinfectants is required.

Artificial disinfectants which destroy the compound, are of various kinds. Fire is one of the most powerful. A putrid body, when heated so as to be deprived of all volatile particles, cannot any longer decompose. It is however possible that the vapours may become putrid, and if not carefully treated, this will happen. It was the custom of some of the wealthy among the ancients to burn the dead, and it is still the custom in India; but although the form is kept up amongst all classes, the expense is too great for the poor. The bodies are singed, or even less touched by fire, and thrown if possible into the river. This process has been recommended here, but the quality of the gaseous matter rising from a dead body, is most disgusting to our physical, and still more to our moral senses, and the amount is enormous. It is of course possible so to burn it, that only pure carbonic acid, water, and nitrogen, shall escape, but the probability of preventing all escape is small enough to be deemed an impossibility, and the escape of one per cent. would cause a ring of the whole neighbourhood. To effect the combustion of the dead of a great city, such a large work, furnished with great and powerful furnaces, would be required, that it would add one of the most frightful spots to modern civilisation, instead of the calm and peaceful churchyard where our bones are preserved as long at least as those who care for us live, and then gradually return to the earth. In burning the dead some prefer to burn the whole body to pure ash. This was the ancient method; but it is highly probable that the ashes which they obtained were a delusion in most cases. The amount of ash found in the urns, is often extremely small. The body cannot be reduced to an infinitesimal ash, as is supposed; eight to twelve pounds of matter remain from an average man when all is over. A second plan, is to drive off all volatile matter, and leave

a cinder. This disgusting plan leaves the body black and incorruptible. It can never, in any time known to us, mix with its mother earth, and yet ceases at once to resemble humanity in the slightest degree; it will not even for a long time assist us by adding its composition to the fertility of the soil. The burning of bodies never could have been general, and never can be general. Fire has only a limited use as a disinfectant. It cannot be used in the daily disinfection of the defects of animals, and is applied only occasionally, where the most rapid destruction is the most desirable, either because the substance has no value, or it is too disgusting to exist, or the products after burning are not offensive. There are two methods of using fire, charring or burning to ashes. The second is an act of

Oxidation.—This is effected either by rapid combustion called fire; by slow combustion, the natural action of the air; or by chemical agency, sometimes assisted by mechanical. Slow oxidation in the soil is a process which is desirable in every respect, and it would be well if we could bring all offensive matter into this condition; the ammonia is preserved, or it is in part oxidised into nitric acid and water, both the ammonia and nitric acid being food for plants. Sometimes this process is hastened by mixing up the manure with alkaline substances, raising it in heaps, and watering, by this means forming nitrates, a process performed abundantly in warm countries upon the materials of plants and animals, and imitated even in temperate regions with success. This amount of oxidation destroys a good deal of the carbonaceous substances, and leaves less for the land. It is only valuable when saltpetre is to be prepared.

One of the most thorough methods of oxidation, is by the use of the manganates or permanganates. They transfer their oxygen to organic substances with great rapidity, and completely destroy them. They are therefore complete disinfectants. They destroy the odour of putrid matter rapidly, and oxidise sulphuretted hydrogen, and phosphuretted hydrogen, as well as purely organic substances. As they do this by oxidation at a low temperature, they are the mildest form of the destructive disinfectants, and their application to putrid liquids of every kind will give most satisfactory results. The quantities treated at a time should not be great, and the amount of material used must be only to the point of stopping the smell, or at least not much more, because both pure and impure matter act on the manganates, and an enormous amount of the material may be used in destroying that which is not at all offensive. The manganates do not prevent decay from beginning again. Their use has been patented by Mr. Condy. A similar action takes place with various high oxides and other oxides which are not high. Sometimes, however, a deleterious gas is produced as a secondary result by oxidation, as when sulphuric acid in the sulphates oxidises organic matter, allowing sulphuretted hydrogen to escape. In this case it is highly probable that a true disinfection takes place, or a destruction of the putrid substance, and all offensive purely organic substances; still the amount of sulphuretted hydrogen given off, is of itself sufficiently offensive and deleterious, although not properly speaking an infectious or putrid gas, but an occasional accompaniment.

Nitric acid is another agent of destruction or oxidation, although it has qualities which might cause it to be ranked amongst those which prevent the decomposition by entering into new combinations. But properly speaking, it is not nitric acid which is the disinfectant of Carmichael Smyth, but nitric oxide, which is a powerful oxidiser, and most rapidly destroys organic matter. For very bad cases, in which gaseous fumigation is applicable, nothing can be more rapid and effective in its action than this gas. Care must be taken that there is no one present to breathe it, as it has a powerful action on the lungs, and care must be taken that metallic surfaces which are to be preserved clean, be well covered with a coating of varnish. This was used with great effect in ships and hospitals for some years, beginning with 1750, and so much good did it do, that the Parliament in 1802 voted Dr. C. Smyth a pension for it. Guyton-Morveau was vexed at this, and wrote an interesting volume concerning his mode of fumigating by acids; but in reality acids alone are insufficient, and his favourite muriatic acid has no such effect as nitrous fumes, which so readily part with their oxygen.

Chlorine is another destructive agent, and its peculiar action may be called an oxidation. When used as a gas, it has a great power of penetration, like nitrous fumes, and stops all putrefaction. It has a more actively destructive power than oxygen alone, even when its action is that of oxidation only. It decomposes compounds of ammonia into water and nitrogen, and as putrefactive matter is united with, or composed partly of nitrogen, it destroys the very germ of the evil. By the same power it destroys the most expensive part of a manure, the ammonia. It cannot therefore be used where the offensive matter is to be retained for manure. When chlorine is united with lime or soda, it may be used either as a powder in the first case, or as a liquid in either case. For direct application to the offensive substances a solution is used, or the powder. This latter acts exactly as the gaseous chlorine, but the

power of destroying ammonia is greater. As a liquid, it acts too rapidly; as a solid, the chloride of lime soon attracts moisture, and soon loses its power. Some people use the chloride of lime as a source of chlorine; they pour sulphuric acid on it, and so cause it to give out chlorine, which escapes as a gas, and acts as aforesaid. This has not been found agreeable, or indeed more than partially useful. Too much is given out at first, too little at last. It is said to have increased the lung diseases at hospitals, where it was much used in Paris. When only a minute quantity of gas is given out, as at bleach works, it certainly causes a peculiar freshness of feeling, and the appearance of the people to much in its favour, nor has it ever there been known to affect the lungs. For violent action, in cases of great impurity, it is a great disinfectant, and to be preferred to nitrous fumes, probably causing a less powerful action on the lungs. *Eau de javelle* is a chloride of potash used in Paris. Sometimes oxygen, or at least air, is used alone, to remove both colour and smell, oils having it pumped into them. Sometimes acids alone are used for disinfection. As putrid compounds contain ammonia or organic bases, they may be removed, or at least they may be retained in combination, and in this way restrained from further evaporation. This seems to be the way in which muriatic acid acts, and all other merely acid agents. This acid, so much valued at one time, is now entirely disused, as it ought to be, because it is exceedingly disagreeable to breathe, and destructive of nearly all useful substances which it touches, being at the same time a very indirect disinfectant. Acids poured on putrid matters, no doubt destroy the true putrefaction, but they cause the evolution of gases exceedingly nauseous, and of course unwholesome. This evolution does not last long, but long enough to make them useless as disinfectants when used so strong. Vinegar is the best of the purely acid disinfectants; wood vinegar the best of the vinegars, because it unites to the acidity a little kresote. Vinegar is a very old and well established agent; it has been used in the case of plague and various pestilences from time immemorial. It is used to preserve cataplasms of various kinds. For fumigation no acid vapour used is pleasant except vinegar, and in cases where the impurity is not of the most violent kind, it may be used with great advantage. Even this however acts on some bright surfaces, a disadvantage attending most fumigations.

Sulphurous acid, or the fumes of burning sulphur, may be treated under this head, although in reality it does not act as a mere acid combining with a base and doing no more. It certainly unites with bases so that it has the advantage of an acid, but it also decomposes by precipitating its sulphur, as when it meets sulphuretted hydrogen. It therefore acts as an oxidiser in some cases, but it is generally believed, from its desire to obtain oxygen, that it acts by being oxidised, thus showing the peculiar characteristics of a deoxidiser. We can certainly believe that bodies may be disinfected both by oxidation and deoxidation. The solutions of sulphurous acid act as a restraint on oxidation, and preserve like vinegar. Its compounds with bases, such as its salts of soda, potash, &c., preserve also like vinegar, saltpetre, &c., probably from their affinity for oxygen, taking what comes into the liquid before the organic matter can obtain it. But it is not probable that this rivalry exists to a great extent; the presence of the sulphurous acid in all probability puts some of the particles of oxygen in the organic matter in a state of tension or inclination to combine with it, so that the tension of the particles which are inclined to combine with the oxygen of the air is removed.

Sulphur fumes are amongst the most ancient disinfectants held sacred in early times from their wonderful efficacy, and still surpassed by none. With sulphur the shepherd purified or disinfected his flocks, and with sulphur physicians disinfected the suitors which he had slain in his house. No acid fumigation is less injurious generally, vinegar excepted, to the lungs or furniture, and its great efficiency marks it out as the most desirable, although much laid aside in modern times. The amount arising from burning coal must have a great effect in disinfecting the putrid air of our streets, and rendering coal-burning towns in some respects less unpleasant; this is one of the advantages which that substance brings along with it, besides, it must be confessed, greater evils. It is curious that this compound of sulphur should be one of the most efficient agents in destroying sulphuretted hydrogen, another compound of sulphur. Sulphurous acid prevents decomposition, and also preserves the valuable principle of a manure, so that it belongs partly to the class of disinfectants, and partly to antiseptics.

The peculiar actions of sulphurous acid and kresote have been united in that called "McDonnell's Disinfecting Powder." Since in towns and farms, when disinfectants are used, it is desirable not to use liquids, these two have been united into a powder, which assists also in removing moisture, as water is often a great cause of discomfort and disease in stables and cow-houses. When they are used in this manner the acids are united with lime and magnesia. When the floors of stables are covered with the powder, it becomes mixed with the manure, which does not lose ammonia, and is found afterwards much more valuable for land. The cattle are also freed from a great

amount of filth, because the air of the stable is purified. When filth of any kind cannot be at once removed by water, as by the water-closet system, the use of this is invaluable; but it is well to know that the instant removal of impurity by water is generally best for houses, however difficult the after problem may be when the river is polluted. In stables and cow-houses this is not the case, and it is then that a disinfecting powder becomes so valuable, although it is true that so many towns are unfortunately so badly supplied with water-closets that disinfectants are still much wanted for the middens.

The inventors have proposed to disinfect sewers, as well as sewage, by the same substances; not, however, in the state of a powder. They apply the acids to the sewage water in the sewers themselves, and so cause the impure water to pass disinfected through the town; by this means the towns and sewers are purified together. When the sewage water is taken out of the town it can be dealt with either by precipitation or otherwise. As it will cease to be a nuisance, covered passages for it will not require to be made.

lime is used for precipitating sewage water, and acts as a disinfectant as far as the removal of the precipitate extends, and also by absorbing sulphuretted hydrogen, which, however, it allows again to pass off gradually. The other substances proposed for sewers have chiefly relation to the precipitation, and do not so readily come under this article. Charcoal has been mentioned; alum has been proposed, and it certainly does act as a disinfectant and precipitant. None of these substances have been tried on a great scale excepting lime. An account of the Leicester experiment by lime will come under the article *SEWAGE*.

Absence of air is an antiseptic of great value. The process of preserving meat, called Appert's process, is by putting it in tin vessels with water, boiling off a good deal of steam, to drive out the air, and then closing the aperture with solder. Schroeder and De Dusch prevented putrefaction for months by allowing no air to approach the meat without passing through cotton; so also veils are found to be a protection against miasmata. *Salts*, or compounds of acids with bases, are valuable antiseptics; some of them are also disinfectants, that is, they remove the state of putrefaction after it has begun. An antiseptic prevents it, but does not necessarily remove it. Common salt is well known as a preserver of flesh; nitrate of potash, or saltpetre, is a still more powerful one. Some of these salts act in a manner not noticed when treating of the preceding substances, viz. by removing the water. Meat, treated with these salts, gives out its moisture, and a strong solution of brine is formed. Chloride of calcium prevents, to some extent, the putrefaction of wool. Alum, or the sulphate of alumina, is not a very efficient preserver; but chloride of aluminium seems to have been found more valuable. It is sometimes injected into animals by the carotid artery and jugular vein. Meat, usually keeps a fortnight; if well packed, cleaned, and washed with a solution of chloride of aluminium, it will keep three months.

But in reality the salts of the heavier metals are of more activity as disinfectants. It has been supposed that their efficiency arose from their inclination to unite with sulphur and phosphorus, and there is no doubt that this is one of their valuable properties, by which they are capable of removing a large portion of the impure smell of bodies; but they have also an inclination to combine with organic substances, and by this means they prevent them from undergoing the changes to which they are most prone. The actual relative value of solutions it is not easy to tell. Most experiments have been made on solutions not sufficiently definite in quantity. Salts of mercury have been found highly antiseptic. Such a salt is used for preserving wool; the process is known as that of Kyan's, or kyanising. A solution of corrosive sublimate, containing about 1 per cent. of the salt, is pressed into the wool either by a forcing pump or by means of a vacuum. The albumen is the substance most apt to go into putrefaction, and when in that condition it conveys the action to the wool. It is no doubt by its action on the albumen that the mercury chiefly acts. Thin pieces of pine wood, saturated for four weeks in a solution of 1 to 25 water, with the following salts, were found, after two years, to be preserved in this order:—1. Wood alone, brown and crumbling. 2. Alum, like No. 1. 3. Sulphate of manganese, like 1. 4. Chloride of zinc, like 1. 5. Nitrate of lead, somewhat firmer. 6. Sulphate of copper, less brown, firm. 7. Corrosive sublimate, reddish yellow and still firmer. In an experiment, in which linen was buried with similar salts, the linen was quite consumed, even the specimen with corrosive sublimate. Other experiments showed salts of copper and mercury to protect best.—*Gmelin*.

Nevertheless, all these metallic salts are found true preservers under other conditions. Chloride of manganese, a substance frequently thrown away, may be used, as Gay-Lussac and Mr. Turgot have shown, with great advantage, and Mr. Boucherie has shown the value of the acetate of iron. Mr. Boucherie's process is very peculiar.

He feeds the tree, when living, with the acetate of iron, by pouring it into a trough dug around the root. The tree, when cut down, has its pores filled with the salt, and the albumen in the sap is prevented from decomposing. For preservation of vegetable and animal substances, see PICTUREFACTION, PREVENTION OF.

The chloride of zinc of Sir William Burnett is also a valuable disinfectant, and has more power than it would seem to possess from the experiments quoted above. Wood, cords, and canvases have been preserved by it under water for many years. It has the advantage also of being so soluble as to take up less room than most other salts, although liquids generally are inconvenient as disinfectants in many places.

Sulphate of lead is a disinfectant of a similar kind; it lays hold of sulphur, and the base unites with organic compounds. All these metals are too expensive for general use, and can only be applied to the preservation of valuable materials. Even iron is much too dear to be used as a disinfectant for materials to be thrown on the fields as manure. All are apt to be very acid, a state to be avoided in a disinfectant, unless when it is applied to substances in a very dilute state, or in an active peroxid state, and giving out ammonia.—R. A. S.

See also SANITARY ARRANGEMENTS.

DISTILLATION. Distillation consists in the conversion of any substance into vapour, in a vessel so arranged that the vapours are condensed again and collected in a vessel apart.

The word is derived from the Latin *dis* and *still*, I drop, meaning originally to drop or fall in drops, and is very applicable to the process, since the condensation generally takes place dropwise.

It is distinguished from *sublimation* by the confinement of the latter term to cases of distillation in which the product is solid, or, in fact, where a solid is vaporised and condensed without visible liquefaction.

The operation may simply consist in raising the temperature of a mixture sufficiently to evaporate the volatile ingredients; or it may involve the decomposition of the substance heated, and the condensation of the products of decomposition, when it is termed *destructive distillation*; in most cases of destructive distillation the bodies operated upon are solid, and the products liquid or gaseous; it is then called *dry distillation*.

In consequence of the diversity of temperatures at which various bodies pass into vapour, and also according to the scale on which the operation has to be carried out, an almost endless variety of apparatus may be employed.

Whatever be the variety of form, it consists essentially of three parts,—the *retort* or *still*, the *condenser*, and the *receiver*.

On the small scale, in the chemical laboratory, distillation is performed in the simplest way by means of the common glass retort *a*, and receiver *b*, as in fig. 651. The glass

advantage of the glass retort *a* is that it is free of permanent obstruction of the materials within, that it is acted upon or injured by but few substances, and may be cleaned generally with facility. Its great disadvantage is its brittleness.

The retort may be either open, as in fig. 652, or tubulated, as in fig. 651 (*a*).

Retorts should generally be chosen so that the convex is in two parts, the degree of curvature of one part being gradually less than that of the other, so that the

represented in the figure; the part to be heated should, moreover, be as uniform in point of thickness as possible. The tubulated retort is more liable to crack than the plain one, on account of the necessarily greater thickness of the glass in the neighbourhood of the tubulature; nevertheless it is very convenient on account of the facility which it offers for the introduction of the materials.

In charging retorts if plain, a funnel with a long stem should be employed, to avoid soiling the neck with the liquid to be distilled; when a solid has to be introduced it is preferable to employ a tubulated retort; and if a powdered solid is to be mixed with a fluid it is preferable to introduce the fluid first.

Heat may be applied to the retort either by the argand gas flame, as in *fig. 654* or a water, oil, or sand-bath may be employed.

In distilling various substances, *e. g.* sulphuric acid, great inconvenience is experienced, and even danger incurred, by the phenomenon termed "bumping." This consists in the accumulation of large bubbles of vapour at the bottom of the liquid, which bursting cause a forcible expulsion of the liquid from the retort. It is prevented by the introduction of a few angular fragments of solid matter of such a nature as not to be acted upon by the liquid which is to be distilled. Nothing answers this purpose better than a piece of platinum foil cut into a fringe, or even a coil of platinum wire introduced into the cold liquid before the distillation is commenced. Even with this precaution the distillation of sulphuric acid, which it is often desirable to perform for the purpose of its purification, is not unattended with difficulty and danger.

Dr. Mohr suggests the following method*:—A glass retort of about two pounds capacity, is placed on a cylinder of sheet iron in the centre of a small iron furnace, while its neck protrudes through an opening in the side of the furnace (*fig. 653*). Ignited charcoal is placed round the cylinder, without being allowed to come in contact with the glass, and a current of hot air is thus made to play on all parts of the retort excepting the bottom, which is protected by its support. There is a valve in the flue of the furnace for regulating the draught, and three small doors in the cupola or head, for supplying fresh fuel on every side, and for observing the progress of the distillation.

Instead of the sheet iron cylinder a hassian crucible may be employed, and this, if requisite, elevated by placing it on a brick. If the vapour be very readily condensed, nothing more is necessary than to insert the extremity of the retort into a glass receiver as in *fig. 651*.

If a more efficient condensing arrangement be requisite, nothing is more convenient for use on the small scale than a Liebig's condenser, shown in *fig. 654*. It consists

simply of a long glass tube into which the neck of the retort is fitted, and the opposite extremity of which passes into the mouth of the receiver; round this tube is fitted another either of glass or metal, and between the two a current of water is made to flow, entering at *a* and passing out at *b*. The temperature of this water may be lowered to any required degree by putting ice into the reservoir *c*, or by dissolving salts in it. (See FREEZING.)

Even on the small scale it is sometimes necessary to employ distillatory apparatus constructed of other materials besides glass.

* Mohr and Reibwood's Practical Pharmacy.

Earthenware retorts are now constructed of very convenient sizes and shapes. There is one kind — which is very useful when it is required to pass a gas into the retort at the same time that the distillation is going on, as in the preparation of chloride of aluminium, &c. — which has a tube passing down into it also made of earthenware, as in *fig. 655*. The closest are of Wedgewood ware, but a common clay retort may be made impermeable to gases, by washing the surface with a solution of borax, then carefully drying and heating them.

Retorts, or flasks with bent tubes, which screw in thus (*fig. 656*), of copper, or

655

656

employed when it is requisite to produce high temperatures, as for the preparation of benzole from benzoic acid and baryta, or in making marsh gas from an acetate, &c.

In distilling hydrofluoric acid the whole apparatus should be constructed in lead; the receiver consisting of a U-shaped tube of lead, which is fitted with leaden stoppers so as to serve for keeping the acid when prepared; or a receiver of gutta percha may be employed with a stopper of the same material. (*Fig. 657.*)

For many purposes in the laboratory as, for instance, the preparation of oxygen by heating binoxide of manganese, — in the manufacture of potassium, &c. &c. where high temperatures are required, the iron bottles in which the fury is imported from

657

658

Spain may be employed, a common gun-barrel being screwed to them to act as a delivery tube or condenser. (*Fig. 658*.)

On a large scale an almost endless variety of stills have been and are still employed, which are constructed of different materials.

The common "gill" consists of a retort or still proper, in which the substance is heated; and a condenser commonly called a "worm" in account of its having frequently a spiral shape. The retort or still is generally made in two parts, the pan or copper, which is the part to which heat is applied, and is commonly set in a furnace of brickwork, and the "head," which is generally removed after each distillation, and refixed and luted upon the pan when again used. The condenser or worm is commonly placed in a tub or other vessel of water. (See *fig. 661*.)

The still may be either constructed of earthenware, or, as is very commonly the case, of copper, either plain or electro-plated with silver, according to circumstances; but frequently platinum is employed.

The still is either heated by an open fire, as in *fig. 658*, or, as is now very commonly

the case, by steam. The still-pan (fig. 659) is surrounded by an outer copper jacket, and steam is admitted between them from a steam boiler under any required pressure. In this way the temperature may be regulated with the greatest ability.

659

Various adaptations for heating by steam have been appropriately arranged in a very convenient form by Mr. Colley, of Bankhill Row, Finsbury, in his so-called *Isenclapian Still*. It is in fact a veritable *mulum in parvo*, being intended to afford to the pharmaceutical chemist the means of conducting the processes of ebullition, distillation, evaporation, decalcination, &c., on the small scale, by the heat of a gas-furnace. The following cut (fig. 660) represents this apparatus.

660

n, a burner supplied with gas by a flexible tube. c, the boiler or still. i, an evaporating pan fixed over the boiler and forming the top of the still-head. k, a

valve for shutting off the steam from *t*, when it passes through the tube *x*, otherwise it would pass through *z*, and communicate heat to the drying closet *o o*, and from thence to the condenser *t r*. *o* is a second evaporating pan over the drying-closet. Another arrangement for distilling by steam is shown in *fig. 661*.

Sometimes also distillation is effected by passing hot steam through a worm contained within the still, instead of or in addition to, the application of heat from without.

The worm or condenser is frequently constructed of earthenware, and set in an earthenware vessel, these are very convenient when the operation is not to be conducted on a very large scale, and only at a moderate temperature. They are now to be obtained of all manufacturers of stone-ware articles. More commonly the worm is of copper, tin, or copper lined with silver, and in some rare cases where the liquids to be distilled act upon both copper and silver, of platinum. (*Fig. 662*.)

A tube of the shape shown in *fig. 663* is still more convenient than the worm, on account of its exposing a larger surface, and also because it can be placed in a

vessel of a prismatic form which occupies but little space: the water employed for condensation enters at the bottom and issues out at the top.

Gadde's condenser is represented in *fig. 664*. It is composed of two parallel sheets of metal, of unequal size, the smaller being fixed with a screw, and the space between

them closed at the bottom. These are placed in a tub filled with cold water, which comes in contact with the inner and outer surfaces of the cones, while the space between is occupied by the vapour to be condensed. This condenser is subject to the objection which applies to the common worm, that it cannot be easily and efficiently cleaned.

To obviate this, Professor Mitscherlich has proposed a very simple modification in its form, in which the inner cone is movable, so that, when taken out, the intervening space between it and the outer cone can be cleaned, and then the inner cone replaced previously to commencing an operation.

Distillation of Spirits.—In the manufacture of ardent spirits, the alcoholic liquor obtained by fermentation of a saccharine solution is submitted to distillation; the alcohol being more volatile than the water passes over first, but invariably a considerable proportion of water is evaporated and condensed with the alcohol. To separate this water to the required extent it is necessary either to submit the product to redistillation, or to contrive an apparatus such that the product of this first distillation is returned to the still until a spirit of the required strength is obtained.

One of the earliest and simplest contrivances for effecting the latter object is the still invented by Dorn, which is employed up to the present time in Germany (*fig 665*). *a* is the still, heated by the direct action of the fire; *b* the head, from which is conveyed vapour to a small refrigerator, for the purpose of testing the strength of the distillate; *c* is an ordinary condenser containing worm, &c. The intermediate copper vessel answers two purposes; the upper part *c* forming a heater for the wash, while the lower compartment *d* acts as a rectifier. The heater *c*, when filled up to the level of the

665

cock *m*, contains the exact measure of wash for charging the still; the contents can be constantly agitated by the rouser *z*. The still and head being both charged, the vapour will at first be completely condensed in passing through the worm *g*, and flowing into *h* will close the aperture. When the contents of *c* become so hot that no further condensation occurs, the vapour will escape by bubbling through the liquid in *n*, which latter rapidly becomes heated to the boiling point, and evolves vapours richer in alcohol, which in their turn are condensed in *n*.

In this manner, by one operation, spirit containing about 60 per cent. of alcohol is obtained.

Of the recent improvements on Dorn's still two only need be described:—Coffey's, which has in a great measure replaced all others in this country, and Deroane's, which is extensively employed in France.

Coffey's still far surpasses any of those before described. It was patented in 1832, and has proved most valuable to the distiller, since it yields the strongest spirit that can be obtained on the large scale.

Its objects are twofold:—1st, to economise the heat, as much as possible, by exposing the liquid to a very extended heated surface; 2nd, to cause the evaporation of the alcohol from the wash by passing a current of steam through it.

The wash is pumped from the "wash charger" into the worm tube, which passes from top to bottom of the rectifier. In circulating through this tube its temperature is raised to a certain extent. Arrived at the last convolution of the tube in the rectifier the wash passes by the tube *x* *y* *z* at the top of the "analyser." It falls and

Improved Apparatus of James C. Jeffrey and Son, of Halesley, near Hove, for the Distillation of Spirit.

collects upon the top shelf until this overflows, whence it falls on to the second shelf and so on to the bottom. All the while steam is passed up from the steam boiler through fine holes in the shelves, and through valves opening upwards. As the wash gradually descends in the analyser it becomes rapidly weaker, partly from condensation of the steam which is passed into it, and partly from loss of alcohol, either evaporated or expelled by the steam; till, when it arrives at the bottom, it has parted with the last traces of spirit. At the same time the vapour, as it rises through each shelf of the analyser, becomes continuously richer in alcohol, and contains less and less water in consequence of its condensation; it then passes from the top of the analyser in at the bottom of the lower compartment of the rectifier. Here it ascends in a similar way, bubbling through the descending wash, until it arrives at a, above which it merely circulates round the earlier windings of the wash pipe, the low temperature of which condenses the spirit, which, collecting on the shelf at r, flows off by the tube into the finished spirit condenser.

In order still further to economise heat, the water for supplying the boiler is made to pass through a long coil of pipe, immersed in boiling hot spent wash, by which means its temperature is raised before it enters the boiler. In fact the saving of fuel by the employment of this still is so great, that only about three-fourths of the quantity is consumed that would be requisite for distilling any given quantity of alcohol in the ordinary still; and Dr. Muspratt estimates that in this way a saving will be effected throughout the kingdom of no less than 140,000 tons of coal per annum.

Very few persons have any idea of the enormous size of some of the distilleries. One of Mr. Coffey's stills at Inverkeithing works off 20000 gallons of wash per hour, and one, more recently erected at Leith, upwards of 3000 gallons.

Derome's still is very similar, in the principle of its action, to Coffey's, differing in

667

fact only in the mechanical details by means of which the result is obtained.

It consists of two stills, A and a, fig. 667. The mixture of steam and alcohol vapour from a passes into the liquid in n, which it raises to the boiling point. The vapours from a rise through the *distillatory column* c, and p (the *rectificatory column*); hence they traverse the coils of tubing in x (the *condenser and wine heater*), and the alcohol is finally condensed by traversing the worm in r (the *refrigerator*), whence it is delivered at z. At the same time a steady current of the original alcoholic liquor is admitted from the reservoir n, to the exterior portion of the condenser r, by means of the tap, the flow from which is regulated by the ball cock g. Whilst condensing the spirit in the worm the wash has its temperature raised, especially in the upper part, and thence it ascends by the tube A into the heater x, by the small orifices A A, fig. 668, where F is still further heated by the current of heated alcohol which has risen into the worm from the stills, whilst at the same time assisting in the condensation of the spirit. After performing its office of condensation,

and when nearly at the boiling point, the alcoholic liquor passes out by the tube l, and

is conducted to the top of the distillatory column *c*. Here it trickles down over a series of lenticular discs of metal (shown in *fig. 66*), so contrived as to retard its

progress into the still *n*, and yet permit the ascent of the steam. In this distillatory column (*c*, *fig. 670*) it meets the steam rising from the still *n*. The greater part of its alcohol is expelled, which, traversing the series of condensers before described, is ultimately liquefied and collected at *x*; but, to complete the rectification, it descends into the still *n*, and, when above a certain level (*m m*), into *a*, which stills being heated by a furnace beneath, the final expulsion of alcohol is accomplished, and the spent liquor run off at *r*.

The details of the construction of the apparatus employed in the distillation of spirits have been here given, since this process is perhaps one of the most important of the kind; but various modifications are employed in the distillation of other liquids.

In some cases, unusually effectual condensing arrangements are required, as in the manufacture of ETHYL, CARBONIC, SULPHURIC, or CHLORINE, and DICHLORIDE OF CARBON.

In others higher temperatures are necessary, as in the distillation of sulphuric acid.

When the liquids to be distilled are acid, or otherwise corrosive, great care has to be taken especially that the worm or other condenser is of a material not acted upon by the acid. See ACETIC ACID, and SULPHURIC ACID.

The term distillation is sometimes applied to cases of the volatilisation and subsequent condensation of the metals either in their preparation or purification.

In cases like mercury, potassium, and sodium, where they are condensed in the liquid state, or visibly pass through this state before volatilisation, this term is quite appropriate; but where the fusing and vaporising points nearly coincide, as in the case of arsenic, the term sublimation would be more suitable.

Nevertheless it is difficult to draw a precise line of demarcation between the two terms; for in the cases of zinc, cadmium, &c., the metals being melted before volatilisation, and condensed likewise in the liquid state, the term is certainly correct.

For the details of construction of the distillatory apparatus we must refer to the articles on these several metals.

Distillate per descensum is a term improperly applied to certain cases of distillation where the vapour is dense, and may be collected by descending through a tube which

has an opening in the top of the distillatory vessels, and descends through the body of the vessel in which the operation of evaporation is going on, being collected below.

This is clearly merely due to the fact of the vapour being even at a high temperature more dense than atmospheric air, and might be performed with any body forming a dense vapour, such as mercury, iodine, zinc, &c.

It has, however, practically been confined to the English process of refining zinc. See ZINC.

The two most remarkable cases in which the process of destructive distillation is carried out on a manufacturing scale, are the dry distillation of wood, for the manufacture of wood charcoal, acetic acid, and pyroxic spirit (which see); and of coal for the purpose of obtaining coal gas, and coke. This process will be found fully described in the article on COAL-GAS.

Distillation of Essential Oils or Essences.—The separation of volatile flavouring oils from plants, &c. by distillation with water, will be fully treated under another head. See PERFUMERY, ESSENCES.

Fractional Distillation.—A process for the separation of volatile organic substances (such as oils) is very extensively employed in our naphtha works under this name.

If we have two volatile bodies together, but differing appreciably in their boiling points, we find, on submitting them to distillation in a retort, through the tubulature of which a thermometer is fixed, so that its bulb dips into the liquid, that the temperature remains constant (or nearly so) at the point at which the more volatile constituent of the mixture boils, and the distillate consists chiefly of this more volatile ingredient; and only after nearly the whole of it has passed over, the temperature rises to the point at which the less volatile body boils. Before this point has been reached, the receiver is changed, and the second distillate collected apart. By submitting the first product to repeated redistillation, as long as its boiling point remains constant, the more volatile constituent of the mixture is ultimately obtained in a state of absolute purity. See NAPHTHA.

This method may in fact be adopted when the mixture contains several bodies; and by changing the receiver with each distinct rise of temperature, and repeating the process several times, a fractional separation of the constituents of the mixture may be effected.—H. M. W.

DISTILLATION, DESTRUCTIVE. Organic matters may be divided into two groups, founded on their capability of withstanding high temperatures without undergoing molecular changes. Bodies that distil unchanged form the one, and those which break up into new and simpler forms, the other. The manner in which heat acts upon organic substances differs not only with the nature of the matters operated upon, but also with the temperature employed. We shall study the subject under the following heads:—

1. Apparatus for destructive distillation.
2. Destructive distillation of vegetable matters.
3. Destructive distillation of animal matters.
4. Destructive distillation of acids.
5. Destructive distillation of bases.
6. General remarks.

1. *Apparatus for destructive distillation.*—Destructive distillation on a large scale is most conveniently performed in the cast iron retorts used at gas works. Where quantities of materials not exceeding fifteen or twenty pounds are to be operated on, for the purpose of research, a more handy apparatus can be made from one of the stout cast iron pots sold at the iron wharves. They are semi-cylindrical, and have a broad flange round the edge. The cover should be made to fit in the manner of a saucapan lid. The aperture by which the products of distillation are to be carried away should be of good size, and the exit pipe must not rise too high above the top of the pot before it turns down again. This is very essential in order to prevent the less volatile portions of the distillate from condensing and falling back. The exit tube should conduct the products to a receiver of considerable capacity, and of such a form as to enable the solid and fluid portions of the distillate to be easily got at for the purpose of examination. From the last vessel another tube should conduct the more volatile products to a good worm supplied with an ample stream of cold water. If it be intended to examine the gaseous substances yielded by the substances under examination, the exit pipe of the worm must be connected with another apparatus, the nature of which must depend on the class of bodies which are expected to come over. If the most volatile portions are expected to be basic, it will be proper to allow them to stream through one or more Woulfe's bottles half filled with dilute hydrochloric acid. Any very volatile hydrocarbons of the C_2H_2 family which escape may be arrested by means of bromine water contained in another Woulfe's bottle. The pressure in the Woulfe's bottles must be prevented from becoming too great, or the leakage between

the flange of the pot and its cover will be very considerable. The luting may consist of finely sifted Stourbridge clay, worked up with a little horse dung. A few heavy weights should be placed on various parts of the lid of the pot, so as to keep it close, and render the leakage as little as possible. For the destructive distillation of small quantities of substances, I have been accustomed for a long time to employ a small still made from a glass pot, and having a copper head made to fit it. The luting for all temperatures not reaching above 700 may be a mixture of 1/3th linseed and 2/3th almond meal, made into a mass of the consistence of putty. For the apparatus employed in the destructive distillation of wood, coal, bones, &c., on the large scale, the various articles in this work on the products obtained from those substances must be consulted.

2. *Destructive distillation of vegetable matters.*—The principal vegetable matters which are distilled on the large scale are wood and coal. We shall consider these separately.

Destructive distillation of wood.—The products obtained in the ordinary process of working are acetic acid, wood spirit or methylic alcohol, acetone, pyroxylic, xylite, lignine, paraffine, kresote, or phenic acid, oxyphenic acid, pitch, several homologues of benzole, with ammonia, and methylamine. There are also several other bodies of which the true nature is imperfectly known. The greater part of the above substances are fully described in separate articles in this work. See ACETIC ACID, PARAFFINE, &c.

Peat appears to yield products almost identical with those from wood.

Destructive distillation of coal.—The number of substances yielded by the distillation of coal is astonishing. It is very remarkable that the fluid hydrocarbons produced at a low temperature are very different to those distilling when a more powerful heat is employed. The principal fluid hydrocarbons produced by the distillation and subsequent rectification of ordinary gas tar are benzole and its homologues; see HYDROCARBONS. But if the distillate is procured at as low a temperature as possible, or Boghead coal be employed, the naphtha is lighter, and the hydrocarbons which make its chief bulk belong to other series. See NAPHTHA.

3. *Destructive distillation of animal matters.*—Bones are the principal animal substances distilled on the large scale. The naphthas which come over are excessively fetid, and are very troublesome to render clean enough for use. The products contained in bone oil will be described in the article NAPHTHA. Horn and wool have recently been examined with reference to the basic products yielded on distilling them with potash. Horn under these circumstances yields ammonia and aniline. Wool I find to afford ammonia, pyrrol, butylamine, and aniline. My experiments on feathers, made some years ago, although not carried so far as those on wool, appear to indicate a very similar decomposition.

The products yielded by animal matters, when distilled *per se*, are very different to those obtained when a powerful alkali is added previous to the application of heat. If feathers or wool be distilled alone, a disgustingly fetid gas is evolved containing a large quantity of sulphur. Part of the sulphur is in the state of a sulphide of carbon. But if an alkali be added previous to the distillation, the sulphur is retained, and the odour evolved, although powerful, is by no means offensive. During the whole period of the distillation of ordinary organic matters containing nitrogen, pyrrol is given off, and may be recognised by the reaction afforded with a slip of deal wood dipped in hydrochloric acid. An interesting experiment, showing the formation of pyrrol from animal matters, may at any time be made with a lock of hair, or the feather of a quill. For this purpose the nitrogenous animal matter is to be placed at the bottom of a test tube, and a little filtering paper is to be placed half way up the tube, to prevent the water formed during the experiment from returning and fracturing the glass. The end of the tube is now to be cautiously heated with a spirit lamp, and, as soon as a dark yellowish smoke is copiously evolved, a slip of deal previously mounted with concentrated hydrochloric acid is to be exposed to the vapour. In a few seconds the wood will acquire a deep crimson colour. The fact of the presence of sulphur in wool, hair, or other albuminous compounds of that description, may be made very evident to an audience by the following experiment. Dissolve the animal matter in very concentrated solution of potash in a silver or platinum basin, with the aid of heat. Evaporate to dryness, and raise the heat at the end of the basin to fuse the potash and destroy most of the organic matters. When cold, dissolve in water, and filter into a flask half full of distilled water. To the clear liquid add a little of Dr. Playfair's nitroprusside of sodium; a magnificent purple tint will be immediately produced, indicative of the presence of sulphur. A very small quantity of hair or dandelion will suffice to yield the reaction.

The above remarks on destructive distillation apply principally to highly complex bodies, the molecular constitution of which is either doubtful, or in the case of a numerous substances, or totally unknown, as with coal and shales. The destructive

distillation of organic substances of comparatively simple constitution, such as acids and alkalies, sometimes yields products, the relation of which to the parent substance can be clearly made out. This holds more especially in the case of organic acids; the times too often yield such complex results, that the decomposition cannot be expressed by an equation giving an account of all the products. We shall study a few cases separately.

4. *Destructive distillation of acids.*—The destructive distillation of acids takes place in a totally different manner, according as we have a base present or the operation is carried on without any addition. Many if distilled *per se* undergo a very simple reaction, consisting in the elimination of carbonic acid, and the formation of a *pyroacid*. But if an excess of base be present, the decomposition often results in the formation of a ketone (see ACETONE). We shall offer a few examples of these decompositions. Gallic acid, heated to about 410° Fahr., is decomposed into pyrogallic and carbonic acids, thus:—

There are cases in which the action of heat upon organic acids results in the formation of two substances, not produced simultaneously, but in two epochs or stages. In reactions like this, the first effect is the removal of two equivalents of carbonic acid, and by submitting the resulting acid to heat again, two more are separated. Under these circumstances, it is the second which is generally called the *pyroacid*. As an example we will take meconic acid which breaks up in the manner seen in the annexed equations.

It will be seen that the hydrogen remains unaffected. Perhaps the name *pyromeconic acid* would be preferable to *pyromeconic acid*, inasmuch as it is derived from comenic acid in the same manner as pyrogallic from gallic acid.

But *pyroacids* are not always derived from the parent acid by the mere elimination of carbonic acid; thus muic acid, in passing into pyromuic acid, loses two equivalents of carbonic acid, and six equivalents of water, thus:—

It does not invariably happen that the destructive distillation of acids *per se* results in the formation of a *pyroacid*, the disruption is sometimes more profound, the products being numerous and somewhat complex. Let us take as an illustration a case where all the results can be reduced to an equation. Oxalic acid, when heated in a retort without addition, yields water, oxide of carbon, carbonic and formic acids, in accordance with the annexed equation:—

The admixture of sand, pulverised pumice stone, or any other inert substance in a state of fine division, often remarkably assists in rendering the decomposition more easy and definite. Thus, if pure sand be mixed with oxalic acid, the quantity of formic acid is so increased, that the process is sometimes employed in the laboratory as a means of affording a pure and tolerably strong acid.

We have said that the destructive distillation of acids proceeds in a very different manner according as we operate upon the acid itself, or a salt of the acid. The distillation of the pure salt yields different products to those which are obtained when the salt or dry acid is mixed with a large excess of a dry base (such as quicklime), before the application of heat. If, in the former mode of proceeding, two atoms of the acid are decomposed, yielding a body containing (for four volumes of vapour, see FOAMING) the elements of two atoms of carbonic acid and two of water less than the parent acid, such body is called a ketone. Thus when two atoms of acetate of lime are distilled, the products are one atom of acetone, and two of carbonic acid. Of course the carbonic acid combines with the lime, thus:—

If, however, the salt is not of a very low atomic weight, and the quantities operated on are at all considerable, secondary products are formed, as in the dry distillation of

oxalate of lime, when, if the substance is not in very small quantity, carbon is deposited, and a certain quantity of butyral ($C^4H^7O_2$) is formed, and probably other substances.

As an illustration of the decomposition under one when acids are distilled with a great excess of dry base, we shall select that of benzoic acid, which under the circumstances alluded to yields benzoic acid and carbamate of the base.

5. *Destructive distillation of bases.*—It has been found that the organic bases undergo a much simpler and more direct decomposition when subjected to destructive distillation in presence of alkalis than when they are exposed to heat without admixture. There are two bodies almost invariably found among the resulting products, namely ammonia and pyrrol. In this respect, therefore, the organic alkalies behave like other nitrogenised animal and vegetable products. The decomposition is almost always rather complex, and it is very rare that the products are sufficiently definite to be arranged in the form of an equation. The most common substances found, are the alcohol bases, and these are almost invariably of low atomic weight. One great difficulty connected with researches on this subject, is owing to the fact of its being seldom that the products are in sufficient quantity to enable a thorough knowledge of the molecular constitution to be arrived at. Unfortunately this information is much wanted in consequence of the numerous cases of isomerism to be met with among the alcohol bases. See FORMULAR CHEMICAL. Thus it is difficult, when working on very small quantities, to distinguish between dimethylamine and ethylamine, both of which have the formula C^2H^5N .

It is remarkable that there is a great similarity between the products of the destructive distillation of some of the most unlike nitrogenous substances. This is conspicuously seen in the case of bones, or rather the gelatinous tissues of bones, shale and coal naphtha, and clovebark. An inspection of the following table, compiled from a paper (by the writer of this article), "On some of the Basic Constituents of Coal Naphtha," will render this evident.

Gelatinous Tissues.	Shale Naphtha.	Coal Naphtha.	Clovebark.
Pyrrol.	Pyrrol.	Pyrrol.	Pyrrol.
Pyridine.	Pyridine.	Pyridine.	Pyridine.
Picoline.	Picoline.	Picoline.	Picoline.
Lutidine.	Lutidine.	Lutidine.	Lutidine.
Collidine.	Collidine.	Collidine.	Collidine.
-	Parvaline.	-	-
-	-	Chinoline.	Chinoline.
-	-	Lapidine.	Lapidine.
-	-	Cryptidine.	-
Aniline.	-	Aniline.	-

It is very possible that some of the above bases, having the same formulae, but derived from different sources, will, in course of time, prove to be merely isomeric, and not absolutely identical. The author of this article has quite recently found that the chinoline of coal tar is certainly not identical with that from clovebark. The base from the latter source yields a magnificent and fast blue dye upon silk, when treated by a process which gives no reaction if the coal base be substituted. It is unfortunate that the reaction is with the latter instead of the former, as it would have added one more to the list of gorgeous dyeing materials yielded by coal tar.

6. *General Remarks.*—The tendency of numerous researches, made during the last few years, has been to show that there is no organic substance, capable of resisting high temperatures, which may not be found to exist among products of destructive distillation. By varying the nature of the substance to be distilled, and also the circumstances under which the operation is conducted, we can obtain an almost infinite variety of products. Acids, bases, and neutral substances, solid, liquid, and fluid hydrocarbons, organic positive, negative, and derived radicals, organo-metallic bodies, — all may be produced by the action of high temperatures on more or less complicated bodies. Much has already been done, but the facts at present accumulated relate merely to the superficial and more salient substances. On penetrating further below the surface far more valuable and interesting facts will come to light. — C. G. W.

DIVIDIVI, or *Lebi Duri*, is the pod of a leguminous shrub, which is an indigenous production of Jamaica, and some parts of South America. Mr. Rostkey obtained a mean produce of 6.625 gra. of leather from 60 gra. of dividivi, while the same quantity of the best Aleppo galls yielded only a mean produce of 4.623. It appears too from Sir Humphry Davy's estimate, that 60 gra. of dividivi contain 3.475 gra. or 5.792 per cent. of tannin, and 60 gra. of galls 5.1274 gra. or 8.545 per cent.

Sixty grs. of oak bark yielded only 1.75 grains of leather; whence it follows that it contains but 0.808 of a grain of tannin to the drachm, or not more than 1.34166.

It has been tried as a dye instead of galls or sumach, but its use for this purpose is almost entirely abandoned. See LEATHER.

DIVING BELL. As it is frequently desirable to raise objects from the bottom of the sea or rivers, and to lay the foundation of piers and similar structures, some contrivance was desired to enable man to descend below the water, and to sustain himself while there. The first method adopted was the very simple one of letting down a heavily weighted bell vertically into the water. As the bell descended, the air got overpressed, and the water rose in the bell, but never to the top, and within that space the man was sustained for some time. The air, however, was vitiated by the processes of respiration, and the man had to be drawn up. It is curious to find that as early as 1693 a very complete system of diving without a bell was devised, as the following quotation will show.

A. D. 1693. "William and Mary, by the Grace, &c. &c. Whereas John Stapleton, gentleman, hath by his great study and experience invented a new and extraordinary engine of copper, iron, or other metall, with glasses for light joints, and so contrived as to permit a person enclosed to move and walk freely with under water, and yet so closely covered over with leather as sufficiently to defend him from all the jumbles of it. Also invented a way to force air into any depth of water, whereby the person in the aforesaid engine may be supplied with a continual current of fresh air, which not only serves him for respiration, but may also be useful for continuing a lamp burning, which he may carry about with him in his hand.

Likewise a way to make the same again serviceable for respiration, and by continually repeating the operation, a man may remain a long time under water, in either of the said engines, without any other air than the said engines do containe, whereby he shall be preserved from suffocation if any extraordinary accident should interrupt the current of fresh air afore mentioned."—*Letters Patent. Rolls Chapel. Edited by Bennett Woodcroft.*

The defects were many in this apparatus, and Dr. Halley invented a bell the object of which was to remedy them.

Dr. Halley's bell was of wood coated with lead, and having strong glass windows above, to allow the passage of light to the diver. In order to supply air, a barrel was taken with an open hole in the bottom, and a weighted hose hanging by, and fitting into a hole at the top. From this barrel the air of the bell was supplied as frequently as it became vitiated, the barrels of air being sent down from above. Spalding improved upon Halley's bell, and again Friwald made some improvements on Spalding's, but in principle these bells were all alike. The modern bells are usually large and strong iron bell's, with windows in the upper part. By means of an air pump, placed on the surface, air is sent down to the divers in the bell, and the vitiated air is as regularly removed from the bell by other tubes through which it escapes. These diving bells are lowered by means of cranes, and are moved about in the water by those above, signals being given by the men below. The difficulty of moving this machine, renders it still inconvenient, and recent attempts have been made to obviate this, by the construction of a diving bell upon principles entirely different. This new diving bell, to which the name of *THE NARCISSUS* has been applied, has proved so useful in the construction of some parts of the Victoria Dock, and some works on the Seine, that a full description of it is appended.

The nautilus machine is entirely independent of suspension; its movements are entirely dependent on the will of those within it, and without reference to those who may be stationed without; it possesses the power of lifting large weights, *per se*, and at the same time is perfectly safe, by common care in its operations. This latter is the greatest desideratum of all. These advantages must strike all as combining those requisites of success which have been always wanting in the present known means for constructing works under water.

The form of the machine is not arbitrary, but depends entirely on the nature of the work to be performed, adapting itself to the various circumstances attending any given position. By reference to the annexed figures it will be perceived that when at rest, being entirely engulphed, its displacement of water being greater than its own weight, it must float to the surface (see fig. 671). Entering through a man-hole at the top (which is closed either from the inside or outside), you descend into the interior of the

machine, portions of which are walled off on either side, forming chambers; these chambers are connected at or near the bottom of a pipe *a* *w*, which opens by a

cock *b*, outwards to the external surrounding water. An opening in the bottom of the machine of variable dimensions is closed by a door or doors susceptible of being opened or closed at pleasure. The chambers *w* *w*, are likewise connected at top by a

a smaller pipe *c* *c*, which opens through the top of the machine, and to which opening is affixed a flexible pipe, with coils of wire spirally connected. Branches on this latter pipe *r*, allow also communication with the larger or working chamber.

At the surface of the water placed on a float or vessel for the purpose, is a receiver of variable dimensions, to which is attached at one end a hollow drum or reel, to the barrel of which is affixed the other end of the flexible pipe *a*, leading to the top of the nautilus. At the other end of *of*, and in connection with the receiver, is a powerful air-condensing pump. This combination represents the nautilus as adapted to engineering work.

As to the *modus operandi* :— The operator with his assistants enters the machine through the top, which is then closed. To descend, the water-cock *b* is opened, and the external water flows into the chambers *w* *w*, at the same time a cock, on a pipe

opening from the chambers outwards, is opened, in order that, the air escaping, an uninterrupted flow of water may take place into the chambers. The weight of water entering the chambers causes a destruction of the buoyancy of the machine, and the nautilus gradually sinks. As soon as it is fairly under water, in order that the descent may be quiet and without shock, the water-cock *b*, is closed. The receiver at the surface being previously charged by the air pump to a density somewhat greater than that of the water at the depth proposed to attain, one of the branch-cocks on the pipe *c c*, connecting the chambers at top, is opened, and the air rushes into the working chamber, gradually condensing until a density equal to the density of the water without is attained; this is indicated by proper air and water gauges. These gauges marking equal points, showing the equilibrium of forces without and within, the cover to the bottom *z* is removed or raised, and communication is made with the under water surface, on which the nautilus is resting. In order to move about in localities where tides or currents do not affect operations, it is only necessary for the workman to step out of the bottom of the nautilus, and placing the hands against its sides, the operator may move it (by pushing) in any direction.

Where currents or tides, however, have sway, it becomes necessary to depend upon fixed points from which movements may be made in any direction. This is accomplished by placing, in the bottom of the nautilus, stuffing boxes of peculiar construction (x u, fig. 672), through which cables may pass over pulleys to the external sides, thence up through tubes (to prevent their being worn, to and over oscillating or swinging pulleys, placed in the plane of the centre of gravity of the nautilus, and thence to the points of affixment respectively (fig. 673). The object to be gained by having

673

the swinging pulleys in the plane of the centre of gravity of the mass, is to hold the machine steady and to prevent oscillation. Within the machine, and directly over the above stuffing boxes, are windlasses for winding in the cables. By working these windlasses movement may be effected, and of course the number of these cables will depend on the variable character of the situation to be occupied. Having thus secured the means of descending, communicating with the bottom, and of movement, the next point is to ascend. Weight of water has caused a destruction of buoyancy at first, and consequent sinking; if then any portion of this water is removed, an upward effort will at once be exerted exactly proportionate to the weight of water thrown out. The air in the receiver at the surface being constantly maintained at a higher density than that of the water below, if we open the water cock on the top pipe, *c c*, throwing the condensed air from the receiver above directly on to the surface of the water in the chambers, movement and consequent expulsion of the water must take place, and an upward movement of the machine itself, which will rise to the surface.

It is evident that if, previously to the expulsion of the water, the nautilus be affixed to any object below, the power exerted on that object will be exactly proportionate to the weight of water expelled, and the power will continue increasing until, there

being no farther weight to be thrown off, the maximum effect is produced. To apply this power to lifting masses of stone or rock, proper arrangements are affixed to the centre of the opening in the bottom, by which connection can be made with the weight, admitting, at the same time, the swinging around of the object suspended, so that it may be placed in any required position. In the construction of permanent work, or the movement of objects whose weight is known, or can be estimated, a water, or, so called, lifting tube is placed on the side of the water chamber, which indicates the lifting power exercised by the nautilus at any moment. The advantage of this gauge will be recognised, inasmuch as without it the closest attention of the operator, working very cautiously, would be necessary to determine when the weight was overcome; by its aid, however, the operator boldly throws open all the valves necessary to develop the power of the nautilus, watching only the gauge. The water, having reached the proper level indicating the required lifting power, he knows the weight must be overcome, or so nearly so that the valve or cocks may be at once closed, in order that the movement may take place horizontally. A moment's reflection will show that, if there were not an index of this character, carelessness or inattention on the part of the operator, by leaving the cocks open too long, might develop a power greater than required, and the nautilus would start suddenly upward. The expansive power of air, acting upon the incompressible fluid, water, through the opening in the bottom, gives a momentum which, by successive developments of expansion in the working chamber, is constantly increasing in velocity, until, in any considerable depth of water, the result would be undoubtedly of a very serious character. Take, for exemplification, the nautilus in thirty three feet of water, and bottom covers removed, and an equilibrium, at fifteen pounds to the inch, existing between the air and the water at the level of the bottom of the machine. Upward movement is communicated the instant the machine rises in the slightest degree, the existing equilibrium is destroyed, and the highly elastic qualities of air assume preponderance, exerting, from the rigid surface of the water below, an impulsive effort upward in the direction of least resistance. At each successive moment of upward movement the impelling power increases, owing to the increasing disparity between the pressure of air within struggling for escape. The machine, thus situated, becomes a marine rocket (in reality), in which the propelling power is exhausted only when the surface is reached, and a new equilibrium is obtained. It will readily be seen that, were this difficulty not overcome, it would be impossible to govern the nautilus; for, rising with great velocity to the surface, the machine is carried above its ordinary flotation, or water line, a little more air escaping owing to the diminished resistance as that level is passed; the recoil, or surging downwards, causes a condensation of the air remaining in the chamber, a portion of the space previously occupied by air is assumed by water, the impelling power becomes less, the machine settles slightly more by condensation of the air, a larger space is occupied by water, and the nautilus redescends to the bottom with a constantly accelerating movement, seriously endangering the operator by filling more or less with water, according to depth. For many months the difficulties just enumerated baffled all attempts at control. A weight attached could be lifted, but the instant it was entirely suspended, — before the valves could be closed, — upward movement was communicated beyond control. This difficulty at first has been overcome by an arrangement at the bottom of the nautilus, with channels which radiate from the opening in an inclined direction, debouching at the sides of the machine. The moment then that the air, by its expansion from diminished resistance, or by the introduction from above of a greater volume than can be sustained by the water below, reaches, in its downward passage, the level of these channels, following the direction of least resistance, it passes through these channels and escapes into the surrounding water, without of course affecting the movement of the machine in the least.

The pump for supplying air to the diving bell or other suitable vessel is represented at Figs. 674 and 675, and is constructed as follows: — D is a cylinder, opening at the upper part into a chamber or chambers *r*, separated by a partition *n*. On the side of each of these chambers there is a valve *u*, opening towards, and at the upper part of the same are two valves *tt*, opening outwards into the valve chamber *u*. Outside the opening for each of the valves *u*, there is a cup, into which the end of the water supply pipe *x* passes; by this means a small stream of water is supplied to the cup, and is drawn from it into the chamber *r* to supply the waste in the operation of pumping. The valve chamber *u* is covered with a jacket *h*, having a space between it and the valve chamber that is filled with water from the water pipe *x*, which affords a stream of cold water to carry off the heat from the condenser, which is forced into the chamber. The water thus supplied circulates through the tubes in the chamber and round them in the jacket, and thus cools the air in three

tubes; it is then conveyed so as to be usefully employed in a steam boiler, or is allowed to run off. The air and a small quantity of water is forced up from the

674

675

cylinder *b* by the stroke of the piston *c* into the chamber *r*, which is thereby filled with water, and thus the air is expelled therefrom, a small quantity of the water passing with it and covering the valves, by which means they are kept tight and wet. The air and water thus discharged, after passing around the small tubes in the valve chamber and being cooled, are forced outward and conveyed to the condenser. On the return stroke of the piston, the other chamber *v* is filled, and air and water expelled from it in like manner through its valve into the valve chamber. There is always a sufficient quantity of water in the cylinder *b* and chamber *r* to fill the latter when the water is all expelled from the cylinder, by the piston *c* having been driven to one end of it, and when the piston returns to the opposite end of the cylinder the water flows in behind it, and draws in its equivalent in bulk of air and water through the valve *h*. On its return, this is forced out through the valve *A* into the chamber *z*, as mentioned above. The water being non-elastic, if the parts are kept cool enough to avoid raising steam, this process may be continued for any length of time. A transverse section of this apparatus is shown in *fig. 675*.

Figs. 676 and 677 represent the speaking tube and alarm bell above referred to. The construction of this mechanism is as follows:—There is a hollow casting, one portion of which is trian-

gular in form, from one end of which a short tube *a* projects. This tube *a* has a screw cut on it, and a projecting flange at its junction with the triangle. This is screwed into the top of the diving vessel or armour from the inside, and projects through it to allow the coupling of a flexible or other hose to be attached to it. At the opposite angle, and in a line with *a*, there is a tubular projection *b*, provided with a screw to receive a cap *f*, to which is to be attached a piece of hose. Within the tube *f*, and at its junction with *b*, is placed a thin diaphragm of metal or other suitable material *c*, for which purpose, however, a thin silver plate that just fits the bore of the cap *f* is preferred. This diaphragm closes all communication between the diving vessel and the external air. By this means it is easy to converse through any required length of tubing. It may be desirable to fit a stop-cock into the tubular projection *b*, as a precautionary means of preventing the escape of air in the event of a rupture of the diaphragm. The upper part of the triangular enlargement of the speaking tube is tapped for a stuffing box at *g*, within which there is an axis *h*, which runs from side to side of the said enlargement, and through the stuffing box at each side. On this axis *h* is fixed a lever *i* within the said enlargement, which lever communicates with the surface of the water by means of a wire fixed at its reversed end, and running through the whole length of pipe. On the outer extremity of the axis *h* is affixed a hammer, which strikes on a bell *k* connected to the tube, as shown in the drawing. By this means the attention of the operator below may be drawn to the speaking tube when it is required to converse with him from the surface of the water, and the one whose duty it is to attend to the operator below can, by placing their ear at the end of the tube, hear the bell struck below as a signal for communication with them at the surface.

The only parts of the apparatus not yet described are the saw for cutting the tops of piles to an uniform level, the pump which enables the divers themselves to rise to the surface in the event of the flexible hose being detached or injured, and the contrivance for screwing an eye bolt into the side of the sunken vessels.

The arrangement of the saw-frame and connections are shown in *fig. 678*. Only as much of the bottom of the Nautilus is shown as will render the position of the saw understood. *p* is a pile which is required to be cut down to the same level as the others, *z* is the blade of the saw, *n* the framing by which it is stretched, *c*, *r*, the handle which rests on the cross bar *x*; to which is attached the upright part of the handle which is laid hold of by the workmen inside when working the saw *u*, *d*, *v*.

a bent lever with two friction rollers at *r* which guides the saw forwards while making the cut.

The pump for ascending in case of accident to the air hose is not shown in the drawing. It is a simple force pump placed in the working chamber, by which the ballast water in *w w.* *fig.* 672, can be pumped out so as to lighten the apparatus sufficiently to allow of its ascent.

The apparatus for fixing the eye bolts is shown in *fig.* 679. The operation of this apparatus is as follows:—It will be observed the chamber *n* opens outwards to the water, so that when the sliding partition or valve *y* is forced down by the lever *g*, the communication of the water with the chamber *c* is cut off. The lid *z* being removed, a bolt *i* (or other operating tool or instrument) is placed within the chamber *c*; the rod *k* is forced through the stuffing box *l* until the recessed end of the rod contains the end of the bolt; the small rod *j* is then screwed through the stuffing box *m*, until the screw on the end of this rod has become affixed to the end of the bolt contained within the recess at *p*. The lid *z* of the chest is then fastened on, and the partition or valve *y* raised, the stuffing box *m* preventing the escape of air. Communication is thus opened between the chambers *A* and *n*, the latter being open outwards. The rod *k* is now pushed outwards by pressing on the handle *A* through the stuffing box *l*, until the vessel or object to be operated upon is reached, when the operation is per-

709

formed as required. It will be observed that the stuffing box prevents the escape of air out of the bell or the admission of water into it, the stuffing box *m* having the same tendency. After the operation with the tool or instrument is complete, the rod *k* is disconnected by unscrewing the rod *j*, and is drawn into the chamber *A* by means of the handle *A*; the partition or valve *y* is again lowered, and the operations above described are repeated. It will hence be obvious that a number of eye bolts might in this manner be successfully inserted in the side of a sunken vessel from the diving bell, so that by hooking on the "camels" the strain would be so distributed as to prevent injury by the process of lifting the said vessel.

DOCIMACY. From the Greek *δοκιμαζω*, I prove (*Docimasie*, Fr.; *Probiervkunst*, Germ.), is the art by which the nature and proportions of an ore are determined. The art of assaying minerals, the separation of the metal. This analytical examination was originally conducted in the dry way, the metal being extracted from its mineralisers, by means of heat and certain fluxes. But this method was eventually found to be insufficient and even fallacious, especially when volatile metals were in question, or when the fluxes could absorb them. The latter circumstance became a very serious evil, whenever the object was to appreciate an ore that was to be worked at great expense. Bergmann first demonstrated, in an elaborate dissertation, that the humid analysis was much to be preferred; and since his time the dry way has been devoted chiefly to the direction of metallurgic operations, or, at least, it has been employed merely in concert with the humid, in trials upon the small scale.

After discovering an ore of some valuable metal, it is essential to ascertain if its quantity and state of combination will justify an adventurer in working the mine, and smelting its products. The metal is rarely found in a condition approaching to purity; it is often disseminated in a gangue far more bulky than itself; and more frequently still it is combined with simple non-metallic substances, such as sulphur, carbon, chlorine, oxygen, and acids, more or less difficult to get rid of. In these compound states its distinctive characters are so altered, that it is not an easy task either to recognise its nature, or to decide if it can be smelted with advantage. The assayer,

without neglecting any of the external characters of the ore, seeks to penetrate, so to speak, into its interior; he triturates it to an impalpable powder, and then subjects it to the decomposing action of powerful chemical reagents; sometimes, with the aid of alkalies or salts appropriate to its nature, he employs the dry way by fire alone; at others, he calls in the solvent power of acids with a digesting heat; happy, if after a series of labours, long, varied, and intricate, he shall finally succeed in separating a notable proportion of one or more metals either in a pure state, or in a form of combination such that from the amount of this known compound, he can infer, with precision, the quantity of fine metal, and thereby the probable value of the mine. The blow-pipe, skilfully applied, affords ready indications of the nature of the metallic constituents, and it is therefore usually the preliminary test. The separation of the several constituents of the ore can be effected, however, only by a chemist, who joins to the most extensive knowledge of the habits of mineral substances, much experience, sagacity, and precision in the conduct of analytical operations. Under the individual metals, as also in the articles BLOWPIPE, AMAL, METALLURGY, MINER, and ORES, are presented such a copious and correct detail of doctrinal processes, as will serve to guide the intelligent student through this labyrinth.

DOEGLING TRAIN OIL. The oil of the *Isidura contrita*, or Bottle-nose whale.

DOGWOOD. *Cornus sanguinea*, a small underwood known as the wild rose-tree, and as the common Dogwood. Little splinters of this wood are used by the watch-makers for cleaning out the pivot-holes of watches, and by the optician for cleaning deeply-seated small lenses. Its peculiarity is that it is remarkably free from alex. Toothpicks are also manufactured from dogwood.

DOLLY. **DOLLY TURN.** A mining term applied to a tub fitted with a perforated board, the dolly, to which a circular motion is given by a winch-handle, and thus imparts a similar motion to the ore. See MIXING and ORES, DRESSING OF.

DOLOMITE. Magnesian limestone. This rock occurs in very great abundance in various parts of England, especially in Yorkshire, Nottinghamshire, and Somerset. It is largely employed as a building stone.

Karsten infers, from his numerous analyses of dolomite, that in those which are crystallised, the carbonate of lime is always combined in simple equivalent proportion with another carbonate, which may be carbonate of magnesia alone, or combined with carbonates of iron or manganese, and sometimes both. In the uncrySTALLISED varieties of dolomite, the diversity in the proportion of lime and magnesia is indefinite, but such masses must be regarded as mere mixtures of true dolomite and carbonate of lime. Acids do not produce a perceptible effect, except when digested with it in fine powder. Karsten found that distilled water and extracts from dolomites, at a temperature below 32° Fahr., only carbonates of lime, while a dolomitic mass remains undissolved. Hence he regards them as mixtures of dolomite with unaltered carbonate of lime — *Buckel*.

Sulphate of magnesia has been manufactured from dolomite by the large scale.

Dr. William Henry, of Manchester, patented a process of the following kind — Calcine magnesian limestone so as to expel the carbonic acid, then add to the caustic lime and magnesia hydrate by moistening them with water; afterwards add a sufficient quantity of hydrochloric, nitric, or acetic acid, or chloride to dissolve the lime, but not the magnesia, which, after being washed, is converted into oxide by sulphuric acid, or, where the cost is objectionable, by sulphate of iron, which is easily decomposed by magnesia. Or the mixed hydrates of lime and magnesia are to be added to bitters: chloride of calcium is formed in solution, while two portions of magnesia (one from the bitters, the other from the magnesian lime) are left undissolved. Hydrochlorate of ammonia may be used instead of bitters: by the addition of this to the hydrated magnesian lime, chloride of calcium and ammonia remain in solution, while magnesia is left undissolved; the ammonia is separated from the decanted liquor by distillation.

At some chemical works on the Tyne, the dolomites from the coal-mines of Mersey are treated with sulphuric acid, and the sulphate of magnesia (*Epsom salts*) separated from the sulphate of lime by crystallisation.

The dolomite has also been employed by the late Hugh Lee Pattison for the manufacture of the CARBONATE OF MAGNESIA, which see.

DONARIUM. Dr. Bergmann received through Mr. Krantz a mineral from Ilreric in Norway, which is found in the same circumstances that contain wolfram and columbite, and he discovered in it the oxide of a new metal combined with carbonic acid. This metal he calls *Donarium*, after the god Donar, and he assigns to it the symbol — *Do*.

The silicate of the oxide of Donarium, $\text{Do}_2\text{O} \cdot \text{SiO}_2 \cdot x\text{H}_2\text{O}$, is yellowish red, in some fragments passing into brown, in others into yellow; when powdered or powdered, it is light orange. In thin films it is almost transparent, the thicker ones

translucid. Some pieces have a distinctly laminated structure, in which the fracture is more flat, or conchoidal. Its hardness is between that of fluor spar and apatite; its specific gravity = 5.397.

Small films heated in a platinum spoon break down into a dark brown mass, which reassumes an orange colour when cold; the larger pieces lose their transparency. By heating it in a glass tube, watery vapour is driven off. Fragments held by the platinum forceps in the flame of a spirit lamp decrepitate. Heated by the blowpipe on charcoal, it does not melt, a slight vitrification being sometimes observed on the edges, perhaps in consequence of the intermixture of some foreign substance. Fused with soda, the silicic acid is dissolved. The other constituents are seen in the non-transparent mass, by the help of a glass, as small yellow particles. Borax yields a yellow bead, which is colourless when cold. The phosphates produce in the external part of the flame a reddish glass, which is colourless when cold; in the inner part of the flame the bead becomes yellow, and when cold is colourless.

The mineral containing donarium, is readily decomposed by acids, and yields when treated by hydrochloric acid a clear and transparent gelatinous matter. At the same time some carbonic acid is evolved. The colour of the solution is deep yellow, like that of a concentrated solution of iron. The mineral is also affected by diluted acids, even by tartaric acid. After having been exposed to a strong heat, the essential parts of mineral are no longer acted upon even by concentrated acids.

The analysis showed the presence of lime, water, and the new oxide, also some traces of magnesia, manganese, carbonate of soda, and iron.

The oxide of donarium belongs to the class of earthy bodies, and ranks next to a zircon and yttria. The hydrate, which is thrown down by ammonia of a beautiful white colour, becomes yellow, and at last yellowish red, losing its hydrate water in the air. By heat the latter is completely removed, and the oxide, which is insoluble in muriatic acid, can be perfectly deprived by this acid of the contained iron. Analysis showed the constituents to be:—

Silicic acid	-	-	-	-	-	17.625
Oxide of donarium	-	-	-	-	-	71.247
Carbonate of lime	-	-	-	-	-	4.042
Oxide of iron	-	-	-	-	-	0.310
Magnesia and oxide of manganese	-	-	-	-	-	0.214
Potash and soda	-	-	-	-	-	0.303
Water	-	-	-	-	-	6.930

100.641

See *Ure's Dictionary of Chemistry*.

DONKEY ENGINE. A very small engine employed to pump water into boilers. If the use of the donkey engine was more usual than it is we should hear less of steam boiler explosions.

DOOPARA RESIN. A resin obtained in considerable quantities in the East Indies from the *Vateria Indica*, which is used as a fragrant incense in the temples, makes an excellent varnish, and is sometimes called *East Indian Copal*, or *Gum Piney*. — *Sumatras*.

DORNOCK, is a species of figured linen of stout fabric, which derives its name from a town in Scotland, where it was first manufactured for table-cloths. It is the most simple in pattern of all the varieties of the diaper or damask style, and therefore the goods are usually of coarse quality for common household wear. It receives the figure by reversing the flushing of the warp and wool at certain intervals, so as to form squares, or oblong rectangles upon the cloth. The most simple of these is a succession of alternate squares, forming an imitation of a checker board or mosaic work. The coarsest kinds are generally woven as tweels of three leaves, where every thread floats over two, and is intersected by the third in succession. Some of the finer are tweels of four or five leaves, but few of more; for the six and seven leaf tweels are seldom or never used, and the eight leaf tweel is confined almost exclusively to damask.

DUWEE. See **FEATHERS.** Down imported in 1857, 5,204 lbs.

DRAGON'S BLOOD (*Sang dracon*, Fr.; *Drachenblut*, Germ.) is a resinous substance, which comes to us sometimes in small balls of the size of a pigeon's egg, sometimes in rods, like the finger, and sometimes in irregular cakes. Its colour, in lump, is dark-brown red; in powder, bright red; friable; of a shining fracture; specific gravity 1.196. It contains a little benzoic acid, is insoluble in water, but dissolves readily in alcohol, ether, and oils. It is brought from the East Indies, Africa, South America, as the produce of several trees, the *Dracena draco*, the *Pterocarpus nati-*
linus, *Pterocarpus draco*, and the *Calamus rotang*.

Dragon's blood is used chiefly for tingeing spirit and turpentine varnishes, for preparing gold leaf, for tooth tinctures and powders, for staining marble, &c. According to Herberger, it consists of 9.07 parts of red resin called *Dracoma*, 2 of fixed oil, 3 of benzoic acid, 1.6 of oxalate, and 3.7 of phosphate of lime. According to Johnstone, the resin of lamp dragon's blood has the formula $C^{10}H^{10}O$, that of reed dragon's blood, $C^{11}H^{10}O$.

Pereira, enumerates the following varieties of this substance found in commerce —

1. *Dragon's blood in the reed; Dragon's blood in sticks; Sanguis Draconis in baculis.*
2. *Dragon's blood in oral masses; Dragon's blood in drops; Sanguis Draconis in lachrymis.*
3. *Dragon's blood in powder.*
4. *Dragon's blood in the tree; Sanguis Draconis in gramis.*
5. *Lamp Dragon's blood; Sanguis Draconis in massis.*

Besides these, there are *Dragon's blood in cakes*, and *False Dragon's blood in oval masses*.

DRAINING TILES. Burnt clay tiles, generally shaped in section like a horse shoe, about one foot long and two or three inches broad. These are much used to agricultural draining. See *STONE-WARE*.

DRAWING CHALKS. Chalks or crayons are frequently nothing more than the natural production reduced to a convenient form; they are, however, sometimes prepared artificially; a few of these manufactures are named.

The brothers Joel, in Paris, employ as crayon cement the following composition: 6 parts of shellac, 4 parts of spirit of wine, 2 parts of turpentine, 12 parts of a colouring powder, such as Prussian-blue, orpiment, white lead, vermilion, &c., and 12 parts of blue clay. The clay being elutriated, passed through a hair sieve, and dried, is to be well incorporated by trituration with the solution of the shellac in the spirit of wine, the turpentine, and the pigment; and the doughy mass is to be pressed in proper moulds, so as to acquire the desired shape. They are then dried by a stove heat.

In order to make cylindrical crayons, a copper cylinder is employed, about 2 inches in diameter, and $1\frac{1}{2}$ inch long, open at one end, and closed at the other with a perforated plate, containing holes corresponding to the sizes of the crayons. The paste is introduced into the open end, and forced through the holes of the bottom by a piston moved by a strong press. The vermicular pieces that pass through are cut to the proper lengths, and dried. As the quality of the crayons depends entirely upon the fineness of the paste, mechanical means must be resorted to for effecting the object in the best manner. The following machine has been found to answer the purpose exceedingly well.

Fig. 640 is a vertical section through the centre of the crayon mill. Fig. 641 is a view of the mill from above. A, the mill tub, whose bottom is made by a horizontal plate of cast-iron; the sides A being of wood or iron at pleasure. In the centre of the bottom there is a pivot C, screwed into a wicket cast upon the bottom, and which may be strengthened by two cross bars D, made fast to the frame E. F, the mill stone of cast-iron, concave, whose diameter is considerably smaller than that of the vessel A; it is furnished within with a circular basin of wood G, which receives the materials to be ground, and directs them to the holes H, which allow them to pass down the under part of the muller, and the bottom of the tub, to undergo trituration.

By the centrifugal motion, the paste is driven towards the sides of the vessel, rises over the sides of the muller, and comes again through the holes H, so as to be repeatedly subjected to the grinding operations. This millstone is mounted upon an upright shaft I, which receives a rotatory motion from the belt-work K, driven by the wheel L.

The furnace in which some kinds of crayons, and especially the facilius lead pencils, are baked, is represented in Fig. 642, in a front elevation; and in Fig. 643, which is a vertical section through the middle of the chimney.

A A, six tubes of greater or less size, according as the substance of the crayons is a better or worse conductor of heat. These tubes, into which the crayons intended for baking are to be put, traverse horizontally the laboratory B of the furnace, and are supported by two plates C, pierced with six square holes for entering the axes of the tubes A. These two plates are kept upon a common axis D, one of them with a ledge, shuts the cylindrical part of the furnace, as is shown in the figure. At the extremity of the bottom the axis D is supported by an iron fork fixed in the brick-work; at the front it rests on the plate E, and lets through an end about 4 inches square, and to receive a key, by means of which the axis D may be turned round at pleasure, and thereby the two plates C, and the six tubes A, are then exposed alternately to the action of the fire in an equal manner upon each of their sides. At the two extremities

of the furnaces are two chimneys *r*, for the purpose of diffusing the heat more equally over the body of the crayons. *r*, *fig.* 682, is the door of the fire-place, by which the

fuel is introduced; *o*, *fig.* 680, the ash-pit; *k*, the fire-place; *i* holes of the grate which separate the fire-place from the ash-pit; *k*, brickwork exterior to the furnace.

General Lomet proposes the following composition for red crayons. He takes the softest hematine, grinds it upon a porphyry slab; and then carefully elutriates it. He makes it into plastic paste with gum arabic and a little white soap, which he forms by moulding, as above, through a syringe, and drying into crayons. The proportions of the ingredients require to be carefully studied.

CRAYONS OF CHALK, lithographic. Various formulas have been given for the formation of these crayons. One of these prescribes white wax, 4 parts; hard tallow-soap, shellac, of each 2 parts; lamp black, 1 part. Another is, dried tallow-soap and white wax, each 6 parts; lamp black, 1 part. This mixture being fused with a gentle heat, is to be cast into moulds for forming crayons of a proper size. See LITHOGRAPHY.

DRUGGET is a coarse, but rather slight, woollen fabric, used for covering carpets, and as an article of clothing by females of the poorer classes.—*Ure*.

The manufacture of druggets of various kinds has been of late years considerably improved, and carpets, many of them handsomely figured, are now found in common use.

DRY GRINDING. The practice of employing dry stones has been long adopted for the purpose of quickening the processes of sharpening and polishing steel goods. The dry dust from the sand-stone, mixed with the fine particles of steel, being inhaled by the workmen, produces diseases of the pulmonary organs to such an extent, that needle and fork grinders are reported rarely to live beyond the ages of twenty-five or thirty.

Mr. Abraham, of Sheffield, first invented magnetic guards, which, being placed close to the grindstone, attracted the particles of steel, and thus protected the men from their influences. Still they suffered from the effects of the fine sand dust, and the grinders heedlessly abandoned the use of them altogether.

Mr. Abraham devised another plan, which is employed, although only partially, in the Sheffield works. The grindstone is enclosed in a wooden case, which only exposes a portion of the edge of the stone; a horizontal tube proceeds as a tangent from the upper surface of the circle to the external atmosphere. The current of air generated by the stone in rapid revolution, escaping through the tube, carries off with it nearly all the dust arising from the process. It is curious to find so simple a contrivance frequently rejected by the workmen, notwithstanding that sad experience teaches them, that they are thereby exposing themselves to the influences of an atmosphere which produces slowly but surely their dissolution.

DRYING OILS. When oils, especially linseed and nut oils, are boiled with litharge or oxide of lead, they acquire the property of solidifying or drying quickly on exposure to the atmosphere. These are very useful to the painter, as without them the pigments with which they are mixed would remain soft. The oxide of lead appears to establish a state of more easy oxidation in the oils, so that they assume readily the conditions of a resin.

DRY ROT. A peculiar decomposition which takes place in wood, dependent upon a process of oxygenation. See WOOD.

DUCTILITY (*Streckbarkeit*, Germ.) is the property of being drawn out in length without breaking, possessed in a pre eminent degree by gold and silver, as also by many other metals, by glass in the liquid state, and by many semisolid, resinous, and gummy substances. The spider and the silkworm exhibit the finest natural exercise of ductility upon the peculiar viscid secretions from which they spin their threads. When a body can be readily extended in all directions under the hammer, it is said to be malleable, and when into fillets under the rolling press, it is said to be laminable.

Table of the Ductility and Malleability of Metals.

Metals Ductile and Malleable in Alphabetical Order.	Light Metals in Alphabetical Order.	Metals in the Order of their Wire Drawing Ductility.	Metals in the Order of their Lamination Ductility.
Cadmium.	Antimony.	Gold.	Gold.
Copper.	Arsenic.	Silver.	Silver.
Gold.	Bismuth.	Platinum.	Copper.
Iron.	Cerium?	Iron.	Tin.
Iridium.	Chromium.	Copper.	Platinum.
Lead.	Cobalt.	Zinc.	Lead.
Magnesium.	Columbium?	Tin.	Zinc.
Mercury.	Iridium.	Lead.	Iron.
Nickel.	Manganese.	Nickel.	Nickel.
Osmium.	Molybdenum.	Palladium?	Palladium?
Palladium.	Osmium.	Cadmium?	Cadmium?
Platinum.	Rhodium.		
Potassium.	Tellurium.		
Silver.	Titanium.		
Sodium.	Tungsten.		
Tin.	Uranium.		
Zinc.			

There appears to be therefore a real difference between ductility and malleability for the metals which draw into the finest wire are not those which afford the thinnest leaves under the hammer or in the rolling press. Of this fact iron affords a good illustration. Among the metals platinum is the first, it is ductile and is malleable. But the most ductile cannot be wire-drawn or laminated to any considerable extent without being annealed from time to time during the progress of the extension, or rather the sliding of the particles alongside of each other, so as to loosen their lateral cohesion.

DULSE. The *Rhodomenia palmata*. See ALGÆ.

DUNES. Low hills of blown sand, which are seen on the coasts of Cheshire and Cornwall, in this country, and also in many places skirting the shores of Holland and Spain.

DUNGING, in calico printing, is the application of a bath of cowdung, diffused through hot water, to cotton goods in a particular stage of the manufacture. Dyeing and scouring are commonly alternated, and are two of the most important steps in the process. See CALICO PRINTING.

DUTCH LEAF or **FOIL**, a composition of copper and lead, or of zinc and copper-leaf. See ALLOYS, BRASS, and HARDY POWERS.

DUTCH RUSH. *Equisetum Hyemale*. This rush is known also as the *Large branchless Horse-tail*. The dried stems are much employed for polishing wood and metal. For this purpose they are generally imported from Holland.

DYEING (*Tinture*, Fr.; *Färberei*, Germ.) is the art of imparting to and fixing upon wool, silk, cotton, linen, hair, and skins any colour, with sufficient permanency, not to be removed by water or the ordinary dyes to which they are first subjected, and exposed when worked up into articles of ornament or furniture. We shall here consider the general principles of the art, referring, for the particular dye and the manner of

treating the stuffs to be dyed, to the different tinctorial substances in their alphabetical order.

Dyeing, although altogether a chemical process, and requiring for its correct explanation an acquaintance with the properties of the elementary bodies, and the laws which regulate their combination, has been practised from the most ancient times, long before any just views were entertained of the nature of the changes that took place. And it is still practised by many who know very little of chemical science, and, like many of the other chemical arts, its practice is often in advance of the science by which its principles are explainable. The art no doubt originated in the love of distinction inherent in the human mind, inducing man, for its gratification, to stain his dress or his skin with the gaudy colours of the vegetable kingdom. The earliest historical record speaks of coloured garments being worn as marks of distinction for offices both political and religious, and also as marks of favour. Jacob gave his favourite son Joseph a coat of many colours, and Moses speaks of a raiment dyed blue, and purple, and scarlet, and of sheepskins dyed red, circumstances which indicate no small degree of tinctorial skill. He enjoins purple stuffs for the works of the tabernacle and the vestments of the high priests.

In the article CALICO PRINTING, it has been shown from Pliny that the ancient Egyptians cultivated the art of dyeing with some degree of scientific precision, since they knew the use of mordants, or those substances which, though they impart no colour themselves, yet enable white robes (*candida vela*) to absorb colouring drugs (*colorem vorbentibus medicamentis*).

Tyre, however, was the nation of antiquity which made dyeing one of its chief occupations and a staple of its commerce, and it is asserted by all writers upon the subject, that the invention of the celebrated purple dye, known as the Tyrian purple, was made in that city, and the king of Phœnicia, being so captivated with the colour, it is stated that he made it one of his principal ornaments, and it became afterwards, and continued to be for many centuries, a badge of royalty.

The discovery of the purple dye is said to have been made 1500 years before the Christian era. It must have met with a very early and general appreciation, and rapid commercial progress. As we find that, nine years after the above date, the children of Israel, an enslaved people, on their leaving Egypt, had in their possession large quantities of this dye, and it was extensively used by them, a short time after, for the furniture of the tabernacle and the vestments of the priests; and in after years this dye was always named amongst the valuable spoils of war; that it was the dress of royalty at a very early period, is indicated by the mention, amongst the spoils of the Midians collected by the Israelites, of the purple garments worn by their kings.

The juice employed for communicating this dye was obtained from two different kinds of shell-fish, described by Pliny under the names of *purpura* and *buccinum*; and was extracted from a small vessel, or sac, in their throats, to the amount of only one drop from each animal. A darker and inferior colour was also procured by crushing the whole substance of the *buccinum*. A certain quantity of the juice collected from a vast number of shells being treated with sea-salt, was allowed to ripen for three days; after which it was diluted with five times its bulk of water, kept at a moderate heat for six days more, occasionally skimmed to separate the animal membranes, and when thus clarified was applied directly as a dye to white wool, previously prepared for this purpose by the action of lime-water, or of a species of lichen called *fucus*. Two operations were requisite to communicate the finest Tyrian purple; the first consisted in plunging the wool into the juice of the *purpura*; the second, into that of the *buccinum*. Fifty drachms of wool required one hundred of the former liquor, and two hundred of the latter. Sometimes a preliminary tint was given with cochen, the kermes of the present day, and the cloth received merely a finish from the precious animal juice. The colours, though probably not nearly so brilliant as those producible by our cochineal, seem to have been very durable, for Ptolemy says, in his *Life of Alexander* (chap. 36), that the Greeks found in the treasury of the king of Persia a large quantity of purple cloth, which was as beautiful as at first, though it was 120 years old.

The quantity of purple, said to be found by Alexander in the treasury of the king of Persia, is differently stated:—1st, as amounting to 5000 talents; 2nd, as being of the value of 5000 talents; 3rd, as weighing 5000 quintals. Besides these discrepant statements it is not clear whether these values or weights refer to cloth dyed or to the dye drug, although it would be an important fact to know that the dye could be thus preserved for a length of time. Horace celebrates the Laconian dye in the following lines:—

Nec Laconicas mihi
Trahunt honeste purpuras clientæ;

which have been translated as —

"No honourable lady dependents
Spin Lacoonian purple for my use."

Notwithstanding its almost universal use in more ancient times it gradually declined, so that, either from the difficulty of collecting the dye, or the tedious complication of the dying process, so expensive was it that, about the commencement of the Christian era, one pound of the purple wool of Tyre cost, in Rome, about thirty pounds of our money.

Notwithstanding this enormous price, such was the wealth accumulated in that capital, that many of its leading citizens decorated themselves in purple attire, till the emperor arrogated to themselves the privilege of wearing purple, and prohibited its use to every other person. This prohibition operated so much to discourage the curious art as eventually to occasion its extinction, first in the western and then in the eastern empire, where, however, it existed in certain imperial manufactures till the eleventh century.

Gage, Cole, Plumier, Reaumur, and Duhamel have severally made researches concerning the colouring juices of shell-fish caught on various shores of the ocean, and have succeeded in forming a purple dye, but they found it much inferior to that furnished by other means. The juice of the buccinum is at first white; it becomes by exposure to air of a yellowish green bordering on blue; it afterwards reddens, and finally changes to a deep purple of considerable vivacity. These circumstances coincide with the minute description of the manner of catching the purple dye shell-fish which we possess in the work of an eye-witness, Eudocia Macrembolitissa, daughter of the Emperor Constantine VIII., who lived in the eleventh century.

The beautiful purple dye, which is now extracted from guano, is probably closely allied, both in property and appearance, to the Tyrian purple.

Dyeing seems to have been little cultivated in ancient Greece. The people of Athens generally wore woollen dresses of the natural colour, a circumstance forming a peculiarity in that nation, composed of a people who were such lovers of art.

The Romans appear to have bestowed some care upon the art of dyeing. In the games of the circus parties were distinguished by colours. Four of these are described by Pliny, the green, the orange, the grey, and the white. The following ingredients were used by their dyers — A crude native alum mixed with copperas, copperas itself, blue vitriol, alkanet, helen root, or archil, broom, madder, wood, nut-galls, the seeds of pomegranate, and of an Egyptian species.

In Europe the progress of dyeing, as of all other arts, was completely stopped for a considerable time by war and invasion, and did not revive till about the beginning of the thirteenth century, and then so rapidly did its progress extend in some localities, that, towards the beginning of the fourteenth century, there were no less than two hundred dyeing establishments in Florence. At the same time the Italians and Venetians also prosecuted the art of dyeing to a large extent.

The art of printing proved for the dyeing, as well as other arts, its great promoter and propagator. In the middle of the 16th century, *Holbein's Art of Dyeing* was printed, which gave general instructions for dyeing all kinds of fabrics, and laid the foundation for that improvement of this art, which soon after followed throughout Germany, France, and England.

In the east, the art of dyeing did not experience that decline which passed over all the arts of Europe; hence the beautiful dyes of India maintained their high character; and, to this day these dyes are produced by processes differing but little from those practised in the days of Pliny.

The discovery and opening of America to commercial enterprise, formed an era in the history of the art of dyeing, so from that country were introduced a variety of new dye-stuffs, such as logwood, brazilwood, quercitron, cochineal, &c., which, with the discovery of the use of tin as a mordant about the same time, gave the dyers a facility and power of producing such a variety of tints, and of such a durability, and lustre, that it is now difficult to conceive possible to have been produced in former times.

About the same time was discovered the art of using indigo as a dye, which it is believed the ancients only knew as a pigment. The introduction of this dye-stuff into this country met with strong opposition, concerning which a writer in the "Penny Cyclopaedia" says,

"Indigo, the innoxious and beautiful product of an interesting tribe of tropical plants, which is adapted to form the most useful and substantial of all dyes, was actually

* In India was discovered the mode of dyeing Turkey red, which is the most beautiful dye known as well as the richest; it is thus prepared — It was introduced into France and England about the middle of last century, and is now the most valuable article in the dyeing trade.

nounced as a dangerous drug, and forbidden to be used, by our parliament in the reign of Queen Elizabeth. An act was passed authorising searchers to burn both it and logwood in every dye-house where they could be found. This act remained in full force till the time of Charles II.; that is, for a great part of a century. A foreigner might have supposed that the legislators of England entertained such an affection for their native wood, with which their naked fires used to dye their skins in the old times, that they would allow no outlandish drug to come in competition with it. A most instructive book might be written illustrative of the evils inflicted upon arts, manufactures, and commerce, in consequence of the ignorance of the legislature."

More recently another class of dye-drugs have been introduced, and have superseded some of those of the former century; these are bichromate of potash, red and yellow prussiate of potash, manganese, catechu, arsenic, &c.

Colours are not, properly speaking, material; they are impressions which we receive from the rays of light reflected, in a decomposed state, by the surfaces of bodies. It is well known that a white sunbeam consists of an indeterminate number of differently coloured rays, which, being separated by the refractive force of a glass prism, form the solar spectrum, an image divided by Newton into seven sorts of rays; the red, orange, yellow, green, blue, indigo, and violet. Hence, when an opaque body appears coloured, for example, red, we say that it reflects the red rays only, or in greatest abundance, mixed with more or less of the white beam, which has escaped decomposition. According to this manner of viewing the colouring principle, the art of dyeing consists in fixing upon stuffs, by means of corpuscular attraction, substances which act upon light in a different manner from the surfaces of the stuffs themselves. The dyer ought, therefore, to be familiar with two principles of optics; the first relatively to the mixture of colours, and the second to their simultaneous contrast.

Whenever the different coloured rays, which have been separated by the prism, are totally reunited, they reproduce white light. It is evident, that in this composition of light, if some rays were left out, or if the coloured rays be not in a certain proportion, we should not have white light, but light of a certain colour. For example, if we separate the red rays from the light decomposed by a prism, the remaining coloured rays will form by their combination a peculiar bluish green. If we separate in like manner the orange rays, the remaining coloured rays will form by their combination a blue colour. If we separate from the decomposed prismatic light the rays of greenish yellow, the remaining coloured rays will form a violet. And if we separate the rays of yellow bordering on orange, the remaining coloured rays will form by their union an indigo colour.

Thus we see that every coloured light has such a relation with another coloured light that, by uniting the first with the second, we reproduce white light; a relation which we express by saying that the one is the complement of the other. In this sense, red is the complementary colour of bluish green; orange, of blue; greenish yellow, of violet; and orange yellow, of indigo. If we mix the yellow ray with the red, we produce orange; the blue ray with the yellow, we produce green; and the blue with the red, we produce violet or indigo, according as there is more or less red relatively to the blue. But these tints are distinguishable from the orange, green, indigo, and violet of the solar spectrum, because when viewed through the prism they are reduced to their elementary component colours.

If the dyer tries to realise the preceding results by the mixture of dyes, he will succeed only with a certain number of them. Thus, with red and yellow he can make orange; with blue and yellow, green; with blue and red, indigo or violet. These facts, the results of practice, have led him to the conclusion that there are only three primitive colours; the red, yellow, and blue. If he attempts to make a white, by applying red, yellow, and blue dyes in certain quantities to a white stuff, in imitation of the philosopher's experiment on the synthesis of the sunbeam, far from succeeding, he will deviate still further from his purpose, and the stuff will by these dyes become coloured of a depth varying according to the quality of the stuff used; until a full black is produced. Nevertheless, the principle is applicable, and in many cases adopted in practice by blending the yellow, red, and blue rays in order to produce or improve an otherwise imperfect white. When a little ultramarine, cobalt blue, prussian blue, or indigo is applied to bleached goods with the view of giving them the best possible white, if only a certain proportion be used, the goods will appear whiter after this addition than before it. In this case the violet blue forms with the brown yellow of the goods a mixture tending to white, or less coloured than the yellow of the goods and the blue separately were. For the same reason a mixture of prussian blue and ochreous pink, or archal and codbear, is used for whitening of silks in preference to a pure blue, for on examining closely the colour of the silk to be neutralised, it was found by the relations of the complementary colours, that the violet was more suitable than the pure blue alone. The dyer should know, that

When he applies several different colouring matters to stuff, as yellow and blue separately, they will appear green, not because the colouring matters have combined, but because the eye cannot distinguish the points which reflect the yellow from those which reflect the blue, and it is this want of distinction that produces the combined colour. With such a dye the colour will appear of different tints, the blue or yellow prevailing according to the position in which it is placed to the eye, whether seen by reflected or transmitted light, but when the dye applied to the stuff is in chemical union, producing a green, such as arsenite of copper the yellow and blue rays cannot be thus distinguished. Other instances of mixed colours will be seen by examining certain grey substances, such as hairs, feathers, &c. with the microscope, by which it is seen grey colour results from black points disseminated over a coloured or slightly coloured surface. The microscope may be thus usefully applied by the dyer to distinguish whether a colour be the result of a mixed or a combined dye.

The dyer should also be acquainted with the law of the simultaneous contrast of colours. When the eye views two colours close alongside of each other, it sees them differing most, in the height of their tone, when the two are not equally pale or full-bodied. They appear most different, when the complementary of the one of them is added to the colour of the other. Thus, put a green alongside of an orange, the red colour complementary of green being added to the orange, will make it appear ruddier. And in like manner, the blue complementary of orange being added to the green, will make it appear more intensely blue.

It is not sufficient to place complementary colours side by side to produce harmony of colour, the respective intensities having a most decided influence; thus, pink and light green agree, red and dark green also; but light green and dark red, pink and dark green do not, therefore, to obtain the maximum of effect and perfect harmony, the following colours must be placed side by side, taking into account their exact intensity and tint.

Primitive Colour.	Secondary Colours.
Red - - - -	Green - - - -
Blue - - - -	Orange - - - -
Yellow orange - -	Indigo - - - -
Greenish yellow -	Violet - - - -
Black - - - -	White - - - -

Light blue
Yellow
Red

Blue
Red
Yellow
Red
Blue
Yellow
Blue
Red

The mixed contrast gives the reason why a brilliant colour should never be looked at for any length of time, if its true tint or brilliancy is to be appreciated; for if a person looks, for example, at a piece of red cloth for a few minutes, green, its complementary colour is generated in the eye, and adding itself to a portion of the red, produces black, which tarnishes the beauty of the red. This contrast explains why the shade of a colour, may be modified according to the colour which the eye has previously looked at, either favourably or otherwise. An example of the first instance is noticed, when the eye first looks to a yellow substance, and then to a purple one, and as exemplifying the second case looking at a blue and then at a purple.

The relations of dyeing with the principles of chemistry, constitute the theory of the art, properly speaking; this theory has for its basis the knowledge -

1st. Of the nature and properties of the bodies which dyeing processes bring into contact.

2nd. Of the circumstances in which these bodies are brought together, and of the action or retarding their action.

3rd. The phenomena which appear during their action; and,

4th. Properties of the coloured combinations which are produced.

The first of these generalities embrace a knowledge of the preparations, which stuff necessarily undergoes previous to dyeing, and also the preparations of the dye, drug before bringing it into contact with the stuff.

The operations to which stuffs are subjected before dyeing, are intended to separate from them any foreign matters which may have become attached, or are naturally

inherent in the stuff. The former are such as have been added in the spinning, weaving, or other manipulations of the manufacture, and are all removed by steeping in an alkaline lye and washing. The second are the natural yellow colouring substances which coat some of the various fibres, both vegetable and animal; and the chlorophyll, or leaf-green of vegetables. The removal of these is generally effected by boiling in soap and alkaline lyes. A weak bath of soda, in which the stuff is allowed to steep for some time, and then washed in water, is generally the only preparation required for wool, in order that it may take on a uniform dye.

To remove the gummy or resinous matter from silk, it requires boiling in soap lye; however, its removal is not essential to the stuff combining with the dye, as silk is often dyed while the gum remains in it, in which case it is only rinsed in soap lye at a very moderate heat, to remove any foreign matters lubricated in the process of manufacture.

Vegetable fibre, as cotton, has such natural resinous matters that retard the reception of the dye removed by boiling, either with or without alkaline lyes; but the natural dun colour of the fibre is not removed, which from the laws of light and colour already referred to, would interfere with the production of bright light tints; under these circumstances, the natural colour of the fibre has to be previously removed by bleaching, for which see the article, BLEACHING.

The necessary preparation of the dye-drugs within the province of the dyer, is to obtain the colour in a state of solution, so as to allow the fibre to absorb it, and to produce chemical combination, or to get the dye or colour in such a minute state of division as it will penetrate or enter into the fibre of the stuff. These preparations embrace the formation of decoctions, extracts, and solutions, and also in some cases of precipitation, previous to immersing the stuff into the bath. Stuff, chemically considered, have but a feeble attraction for other matters, so as to combine with them chemically; still that they do possess certain attractions is evident from various phenomena observed in the dyeing processes, and that this attraction is possessed with different degrees of intensity by the different fibres, is also evident from the ease and permanence that woollen stuff will take up and retain dyes compared with cotton; and also, that certain dyes are retained and fixed within or upon one kind of fibre and not at all in another. This may be determined by plunging the dry stuff into solutions of the salts, and determining the density of the solution before the immersion and after withdrawing the stuff. Wool abstracts alum from its solution, but it gives it all out again to boiling water. The sulphates of iron, copper, and zinc, resemble alum in this respect. Silk steeped for some time in a solution of potassiumate of iron, abstracts the oxide, and gets thereby dyed, and leaves the solution acidulous. Cotton in citrate of iron produces the same effect. Wool put in contact with cream of tartar, decomposes a portion of it; it absorbs the acid within its pores, and leaves a neutral salt in solution in the liquor. Cotton produces no such effect with tartar, showing by these different effects that there are certain attractions between the stuff and dyes. This attraction, however, may be more what is termed a catalytic influence, the fibres of the stuff producing a chemical action with the salt or dye, with which it is in contact. This attraction or affinity of the fibre for the dye-drug, does not produce a very extensive effect in the processes of dyeing. More probably the power of imbibing and retaining colours possessed by the fibre is more dependent upon a mechanical than a chemical influence.

All dye-drugs must in the first instance be brought into a state of solution, in order that the dye may be imbibed by the fibre; but if the fibre exerts no attraction for the colour so as to retain it, it is evident that so long as it remains capable of dissolving in water, the stuffs being brought into contact with water, will soon lose their colour. A colour thus formed does not constitute a dye, however strongly stained the stuffs may appear to be, in or out the dyeing solution; in order to form a dye, the colour must be fixed upon or within the stuff, in a condition insoluble in water. Hence the mere immersion of the stuff into a solution of a colour will not constitute a dye, except where the stuff really has an attraction for the colour and retains it, or causes a decomposition by which an insoluble compound is fixed upon it, such as referred to by putting stuffs into solutions of iron. The abstraction of the colour from a solution by the immersion of the stuff, is often the result of a mechanical attraction possessed by porous substances, enabling them to absorb or imbibes certain colouring matters from solutions that are held by a weak attraction by their solvents. On this principle, a decoction of cochineal, logwood, brazil-wood, or a solution of sulphate of indigo, by digestion with powdered bone black, lose their colour, in consequence of the enclosing particles combining by a kind of capillary attraction with the porous carbon, without undergoing any change. The same thing happens when well scoured wool is steeped in such coloured liquids; and the colour which the wool assumes by its attraction for the dye, is, with regard to most of the above coloured solutions, but feeble and fugitive, since the dye may be again abstracted by copious washing with

Simple water, whose attractive force therefore overcomes that of the wool. The aid of a high temperature, indeed, is requisite for the abstraction of the colour from the wool and the bone-black, probably by enlarging the size of the pores, and increasing the solvent power of the water.

Those dyes, whose colouring matter is of the nature of extractive, form a faster combination with stuffs. Thus the yellow, fawn, and brown dyes, which contain tannin and extractive, become oxygenated by contact of air, and insoluble in water; by which means they can impart a durable dye. When wool is impregnated with decoctions of that kind, its pores get charged by capillarity, and when the liquid becomes oxygenated, they remain filled with a colour now become insoluble in water. The fixation of iron oxide and several other bases also depends on the same change within the pores or fibre, hence all salts that have a tendency to pass readily into the basic state are peculiarly adapted to act as a medium for fixing dyes; however, this property is not essential.

In order to impart to the stuffs the power of fixing the colour in an insoluble form upon it, recourse is had to other substances, which will combine with the soluble and form with it an insoluble colour; and it is not necessary that this new substance should have an attraction for the stuff, or be capable of passing into a basic form, any more than the original colour, but it is necessary that it be rendered insoluble while in contact with the stuff.

Such substances used to unite the colour with the stuff have been termed mordants, which mean that they had a mutual attraction for the stuff and colour, and combining with the stuff first, they afterwards took up the colour; but this is only so in some instances. A few examples will illustrate the bearing of these mordants. If a piece of cotton stuff is put into a decoction of logwood, it will get stained of a depth according to the colour of the solution, but this stain or colour may be washed from the cotton by putting it into pure water, the colour being soluble. If another piece of cotton stuff be put into a solution of protosulphate of iron, and then washed from this, a portion of the iron will have undergone oxidation, and left the acid, and become fixed upon the fibre and insoluble in water. Whether this oxidation is the result of an influence of the stuff, or the effect of the oxygen of the air and water in which the goods are exposed, it does not matter meantime, only this fixed oxide constitutes an example of a mordant by its combining with the stuff. If this stuff is now put into a decoction of logwood, the colouring matter of the logwood will combine with the oxide of iron fixed upon the fibre, and form an insoluble colour, which after washing will not remove from the stuff. If, instead of washing the stuff from the sulphate of iron solution in water, it be passed through an alkaline lye of soda or potash, the acid holding the iron in solution is taken hold of by the alkali, and removed. The oxide of iron is thus left upon the stuff, in a much larger quantity than in the former case, and is firmly fixed, although not by any attraction between it and the fibre, but simply being left within it. And this stuff being now put into the logwood liquor, will form a dye of a depth according to the quantity of iron thus fixed upon the stuff, and equally permanent with that which had been fixed on the stuff by the oxidation in working.

Such then are the methods of fixing within the stuff insoluble colours from soluble compounds, and from these remarks the necessity of having the dye in solution will also be evident.

Suppose again that the sulphate of iron be mixed with the logwood decoction, there will be produced the same colour or dye as an insoluble precipitate; if the cotton stuff is put into this, no colour worthy of the name of a dye will be obtained, as the cotton will not imbibe within its fibre this precipitate. Place woollen stuff in the same liquid, there is formed a very good dye, the woollen fibre having imbibed a great portion of the solid precipitate, probably owing to woollen fibres being much larger than those of cotton. Thus, with cotton and other stuff that will not imbibe freely solid precipitates, the mordant must be fixed within the fibre previous to applying the colouring substances, such as the vegetable decoctions. It will also be seen that the dye which is the product of combination between the mordant and colour is not that of the natural colour of the drug, but the colour of the compound. Hence the great variety of tints capable of being produced from one dye-drug, by varying either the kind or intensity of the mordant. So that in the above instances, it is not the colour of the hematein fixed on the stuff, but its compound with iron, or tin, or alumina, as the case may be, all of which give different tints.

It is upon this principle of rendering bases insoluble while within the fibre by chemical means, that has brought to the use of the dyer a great number of mineral dyes which in themselves, whether separate or combined, have no attraction whatever for the fibre; such as solutions of sulphate of copper, and yellow prussiate of potash, nitrate of lead, and bichromate of potash, &c. Suppose the stuff to be dyed a yellow

by the two last named salts, was first put into the solution of lead and then washed previous to being put into the bichromate solution, the greater portion of the lead would be dissolved from the stuff, and a very weak colour would be obtained. If the stuff from the lead solution was put directly into the bichromate solution, a very good dye would be the result; but the portion of the solution remaining upon the surface of the stuff will combine with the chrome and form a precipitate which the fibre cannot imbibe, but will form an external crust or pigment upon the surface, which blocks up the pores and exhausts to no purpose the dye, causing great waste: hence the stuff from the solution of lead is put into water containing a little soda or lime, and the lead is thus reduced to an insoluble oxide within the fibre. The goods may now be washed from any loose oxide adhering, and then passed through the bichromate solution, when the chromic acid combines with the oxide of lead, forming a permanent yellow dye. Thus it will be seen that whether the combination of the colour with the stuff be chemical or mechanical the production of the dye which is fixed upon the fibre is certainly a chemical question, and the dyer should be familiar with the nature and principles of these reactions.

There are a few instances where the dye produced does not come within the sphere of these principles, there being no mordants required, nor any combination of the colour formed within the stuff, but the dye-drug in its natural hue is fixed within the fibre. Such colours have been termed *substantive*, to distinguish them from those produced by means of mordants, which are termed *adjective*. Amongst this class of dyes and dye-drugs stands pre-eminent indigo blue. Indigo in its natural state is entirely insoluble in water, and is of a deep blue colour. The composition of this blue indigo is represented as—

Carbon	-	-	-	16	Nitrogen	-	-	1
Hydrogen	-	-	-	5	Oxygen	-	-	2

But it is found capable of parting with a portion of the oxygen, and by so doing, losing entirely its blue colour; and in this deoxidised condition it is soluble in alkaline lyes and lime water; this colourless compound is termed *indigene*. The opinion of Liebig upon the constitution of this substance is, that indigo contains a salt radical, which he terms *anyle*, composed of $C^{14}H^{12}N$. He considers that indigene or white indigo is the *hydrated peroxide* of this radical, and that blue indigo is the *peroxide*, represented thus—

	C	H	N	O	Water
Salt radical, anyle	-	-	-	16	5 1 0 0
Indigene	-	-	-	16	3 1 1 1
Blue indigo	-	-	-	16	3 1 2 0

Advantage is taken of this property of indigo, of parting with its oxygen and becoming soluble, to apply it to dyeing, and it is effected by the following means, when for the purpose of dyeing vegetable stuff, as cotton; and from the circumstance of these operations being done cold, the method is termed the *cold vat*, which is made up as follows:—The indigo is reduced to an impalpable pulp, by being ground in water to the consistence of thick cream. This is put into a suitable vessel filled with water, along with a quantity of copperas, and newly slaked lime, and the whole well mixed by stirring. After a short time the indigo is deoxidised and rendered soluble by a portion of the lime which is added in excess, the reaction being represented thus:—

The peroxide of iron and sulphate of lime are precipitated to the bottom, and the indigene and lime form a solution of a raw colour, with dark veins through it.

The operation of dyeing by this solution is simply immersion, technically, *dipping*. The stuff by immersion imbibes the solution, and when taken out and exposed to the air, the indigene upon and within the fibre rapidly takes oxygen from the atmosphere, and becomes indigo blue, thus forming a permanent dye, without any necessary attraction between the indigo and the stuff.

The indigo vat for wool and silk is made up with indigo pulp, potash, madder, and

bran. In this vat the extracts of madder and bran perform the deoxidising functions of the copperas in the cold vat, by undergoing a species of fermentation.

Indigo and wool, either alone or with the addition of a little indigo, is also used for the dyeing of wool and silk stuff, the deoxidation being effected by the addition of bran, madder and weld. In dyeing with these vats, the liquor is made warm, and they require much skill and experience to manage, in consequence of their complexity, being always liable to go out of condition, as the dyeing goes on, by the extraction of the indigogenes and the modification of the fermentable matter employed to deoxidise the indigo to supply that loss. The alkaline solvent also undergoes change, so there must be successive additions of indigo and alkali; the principal attention of the dyer is the maintaining the proper relation of these matters, as too much or too little of either is injurious.

Sulphate of indigo forms an intense blue solution, unaffected also by mordants. Vegetable stuffs dipped in this retain no dye, for the washing off the acid in order to preserve the fibre removes the colour; but animal fibre, such as woollen and silk, becomes dyed, a portion of the blue remains upon the stuff after washing off the acid, being retained by capillary attraction. This dye is termed *Saxon blue*, but it has very little of the permanence of indigo or *vat blue*, although it is also a substantive colour.

Another truly substantive colour is that dyed by carthamus or safflower, but the fixation of this dye upon the stuff differs from any of those referred to. Like indigo, it has no affinity for any base or substance capable of forming a mordant; its solvent is an alkali, but in this dissolved state it does not form a dye. The mode of proceeding in dyeing with carthamus is first to extract the dye from the vegetable in which it is found, by soda or potash, which is afterwards neutralised by an acid previous to dyeing, which renders the colour insoluble, but in so fine a state of division that no precipitation can be seen for some time and the stuff immersed in this imbibes the colour within its fibre, its lightness assisting this action, as the precipitate will remain suspended in water for days before it will subside. Vegetable fibre takes up this dye as easily as animal, but whether by an attraction for the stuff, or by a mechanical capillary attraction of the fibre is not so easily determined. A piece of stuff suspended in a vessel filled with water, having in it some insoluble carthamine, all the colouring particles will flow to and combine with the fibre from a considerable distance, giving a proof of the existence of some force drawing them together.

Such then are the various conditions and principles involved in the processes of fixing the dye within or upon the stuff.

During the operations of dyeing there are certain circumstances which have to be attended to, in order to facilitate and effect certain hues or tints of colour. Thus, with many of the colouring substances, heat not only favours but is necessary for the solution of the dye, and also its combination with the stuff or mordant. Decortiations of woods are always made by hot water, and the dyeing processes which decorticate are in hot liquor. When the colouring matter of quercitron bark is extracted by boiling water, the colour produced upon the stuff will be a rich amber yellow, but if the extract be made by water at 150° Fahr., a beautiful lemon yellow will be the dye produced by it, using the same mordant in each case. Colours dyed by madder and Barwood must be done at a boiling heat during the whole process, or no dye is effected. Sumach, another astringent substance, is most advantageously applied at a boiling heat; and in order to have a large body of this dye fixed upon the stuff, it should be immersed in the liquor while hot and allowed to cool together, during which the tannin of the dye undergoes some remarkable change in contact with the stuff. Safflower dyes are kept cold, so are tin bases, Prussian blue, and chrome yellows, by applying heat to the last a similar result is effected to that with bark; instead of a lemon yellow an amber yellow will be obtained. Almost all colours are affected less or more by the temperature at which they are produced. Some mordants are fixed upon the stuff by heat, such as acetate of alumina, the stuff being dried from a solution of this salt at a high temperature loses part of the acid by being volatilised, and the residue remains upon the fibre an insoluble suboxide, which fixes the dye. These remarks respecting the methods apply more particularly to vegetable stuffs, as cotton, and in many cases also to silk, but wool is always dyed at a high heat. Although wool seems to have a much greater absorbing power than cotton, the latter will absorb and become strongly dyed in a cold dye bath, in which wool would not be affected; but apply heat and the wool will be deeply dyed, and the dye much more permanent than the cotton.

The permanence of colours is another property to be carefully studied by the practical dyer, as the colour must not be brought under circumstances that will destroy its permanency during any of the operations of the dyehouse. The word permanent, however, does not mean fast, which is a technical term applied to a colour that will resist all ordinary operations of destruction. As for instance, a Prussian

blue is a permanent colour but not a fast colour, as any alkaline matter will destroy it, or a common black is permanent, although any acid matters will destroy it; while Turkey red is a fast colour and not affected by either acid or alkaline matters. A few of the circumstances affecting colours in the processes they are subjected to may be referred to in this place. If, for instance, the air in drying the dyed stuff in a hot chamber be moist, there is a great tendency to the colour being impaired in these circumstances. For example, a red colour dyed with safflower will pass into brown, a Prussian blue will pass into a grey lavender, chrome yellows take an amber tint. Mostly all colours are affected less or more by being subjected to strong heat and moisture; even some of those colours termed fast are affected unless such circumstances. A dry heat has little or no effect upon any colour, and a few colours are made brighter in their tint by such a heat, as chrome orange, indigo blue, on cotton, &c.

Some of these effects of heat and moisture differ with different stuff; thus indigo blue upon cotton is not so much affected as indigo blue upon silk, while safflower red upon cotton will be completely destroyed before the same colour upon silk will be perceptibly affected. The same colouring matter fixed by different mordants upon the same stuff is also differently affected under these conditions.

Light is another agent exerting a great influence upon the permanence of colours, which should be also considered by the dyer. Reds dyed by a Brazil wood and a tin mordant, exposed to the light, become brown; Prussian blue takes a purple tint; yellow becomes brownish; safflower red, yellowish, and these changes are facilitated by the presence of moisture; such as exposing them to strong light while drying from the dye bath, either out or within doors. The direct rays of the sun destroy all dyed colours; even Turkey red yields before that agency.

Dyeing was formerly prescribed in France as a test of fast dyes. It consisted in putting a sample of the dyed goods in boiling water, holding in solution a determinate quantity of alum, tartar, soap, and vinegar, &c. Dubay improved that barbarous test. He considered that fast-dyed cloth could be recognised by resisting an exposure of twelve hours to the sunshine of summer, and to the midnight dews; or of sixteen days in winter.

In trying the stability of dyes, we may offer the following rules:—

That every stuff should be exposed to the light and air; if it be intended to be worn abroad, it should be exposed also to the wind and rain; that carpets moreover should be subjected to friction and pulling, to prove their tenacity; and that cloths to be washed should be exposed to the action of hot water and soap. However, such tests are not at all applicable to most of the colours dyed upon cotton stuff. Not many of them can stand the action of hot water and soap, or even such acids as the juice of fruits. Indigo blue, one of the most permanent dyes on cotton, yields its intensity to every operation of washing, even in pure water.

Delaval's observations on the nature of dyes may be thus summed up. In transparent coloured substances, the colouring substance does not reflect any light; and when, by intercepting the light which was transmitted, it is hindered from passing through substances, they do not vary from their former colour to any other colour, but become entirely black; and he instances a considerable number of coloured liquors, none of them endued with reflective powers, which, when seen by transmitted light, appeared severally in their true colours; but all of them, when seen by incident light, appeared black; which is also the case of black cherries, black currants, black berries, &c., the juices of which appeared red when spread on a white ground, or otherwise viewed by transmitted instead of incident light; and he concludes, that blacked lines, &c. "when dyed with vegetable colours, do not differ in their manner of acting on the rays of light, from natural vegetable bodies; both yielding their colours by transmitting, through the transparent coloured matter, the light which is reflected from the white ground;" it being apparent, from different experiments, "that no reflecting power resides in any of their components, except in their white matter only," and that "transparent coloured substances, placed in situations by which transmission of light through them is intercepted, exhibit no colour, but become entirely black."

The art of dyeing, therefore (according to Mr. Delaval), "consists principally in covering white substances, from which light is strongly reflected, with transparent coloured media, which, according to their several colours, transmit more or less copiously the rays reflected from the white," since "the transparent media themselves reflect no light; and it is evident that if they yielded their colours by reflecting instead of transmitting the rays, the whiteness or colour of the ground on which they are applied would not in anywise alter or affect the colours which they exhibit."

But when any opaque basis is interposed, the reflection is doubtless made by it,

rather than by the substance of the dyed wool, silk, &c., and more especially when each basis consists of the white earth of alum, or the white oxide of tin; which, by their strong reflective powers, greatly augment the lustre of colours. There are, moreover, some opaque colouring matters, particularly the acetons, and other solutions of iron, used to stain linen, cotton, &c., which must necessarily themselves reflect instead of transmitting the light by which their colours are made perceptible.

The compound or mixed colours are such as result from the combination of two differently coloured dye stuffs, or from dyeing stuffs with one colour, and then with another. The simple colours of the dyer are red, yellow, blue, and black, with which, when skilfully blended, he can produce every variety of tint. Perhaps the dun or fawn colour might be added to the above, as it is directly obtained from a great many vegetable substances.

1. Dye with yellow, produces orange; a colour, which upon wool is given usually with the spent scarlet bath. To this shade may be referred flame colour, pomegranate, capuchin, prawn, jonquil, cassia, chambré, *café au lait*, aurora, marigold, orange peel, moorvée, cinnamon, gold, &c. Sauff, chestnut, ink, and other shades are produced by substituting walnut peels or sumach for bright yellow. If a little blue be added to orange, an olive is obtained. The only direct orange dyes are annatto, and subchromate of lead. See SILK AND WOOL DYEING.

The latter is never used for dyeing orange upon silk and wool, while the former is now never used for cotton. An orange upon anwool is very fugitive, even upon the animal fibre; but much more so upon cotton. Subchromate of lead is produced upon cotton by dyeing it first a deep chrome yellow by a state of lead and bichromate of potash, as already noticed, and then passing the stuff so dyed through a hot solution of an alkali or lime, which changes the dye from the yellow chromate to the state of subchromate, which is deep orange.

2. Red with blue produces purple, violet, lilac, pigeon's neck, mallow, peach-blossom, *bleu de roi*, hint-blossom, amaranth.

These are produced by

7. Red with black; brown, chocolate, maroon. &c. These tints are produced by various processes. To dye a deep orange by annatto liquor, and then firm over it a black by sumach and sulphate of iron, gives a brown; or dye the stuff first a rich yellow by quercitron and a tin mordant, and then over the yellow produce a purple by passing it through logwood; chocolates are thus produced. A little Brazil wood with the logwood gives more of the red element. When maroon is required, the red is made to prevail, and so by a judicious mixture, these various tints are produced. Brown, especially upon cotton fibre, is more often produced direct by means of catechu. Steep the stuff in a hot solution of catechu, in which the gummy principle has been destroyed by the addition of a salt of copper; then pass through a solution of bi-chromate of potash at boiling heat, when a rich brown is obtained.

4 Yellow with blue; green of a great variety of shades: such as nascent green, gay green, grass green, spring green, laurel green, sea green, celadon green, parrot green, cabbage green, apple green, dock green.

Green is essentially a mixed dye, and produced by dying a blue over a yellow or a yellow over a blue. In almost all cases the blue is dyed first, and then the yellow, and according to the depth of each or any of these are the various tints of green produced. With silk and wool, one kind of green dye may be produced simultaneously by putting sulphate of indigo into the yellow dye bath, and then working the previously prepared or mordanted stuff in this. With cotton, an arsenite of copper (See note) prepared or mordanted stuff in this. With cotton, an arsenite of copper (See note) prepared or mordanted stuff in this. With cotton, an arsenite of copper (See note) prepared or mordanted stuff in this.

5. Mixtures of colours, three and three, and four and four, produce an indefinite diversity of tints: thus, red, yellow, and blue form brown olives and greenish greys; in which the blue dye ought always to be first given, lest the indigo vat should be soiled by other colours, or the other colours spoiled by the alkaline action of the vat. Red, yellow, and grey (which is a gradation of blue) give the dead-leaf tint, as well as dark orange, saffron colour, &c. Red, blue and grey give a vast variety of shades; as lead grey, slate grey, wood-pigeon grey, and other colours too numerous to specify. See BROWN DYE.

There must be taken, however, in mixing these colours, to study the depth of the tint required; as, for instance, were we wishing to dye a slate grey, and to produce first by dyeing a blue, then a red, with a little of the grey, we would produce, instead of a slate grey, a purple or peach. The arrangement referred to, applied only to the

elements of the colours that enter into the composition of the various tints, so that a slate grey is a blue with a small portion of red, and a still smaller portion of the black element, that produces the grey tint. Thus, dye the stuff first a deep sky blue by the vat, then by passing through a solution of sumach, with a small quantity of logwood, Brazil wood, copperas, and alum, grey will be produced. The Brazil wood gives the red tint, sumach and copperas the black tint, the logwood assisting in this, and with the aid of the alum throwing in the pace or dove neck line; and thus by the variation of these hues by such arrangements, any of the grey tints can be produced. See CALICO PRINTING.

DYER'S ALKANET, *Alkanna tinctoria*. See ALKANET.

DYER'S MADDER, *Rubia tinctorum*. See MADDER.

DYER'S OAK, *Quercus infectoria*. See GALLS and OAK.

DYER'S ORCHELLA WEEED, *Rocella tinctoria*. See ARCHIL, ORCHELLA.

DYER'S SAFFLOWER, or Bastard saffron. *The Carthamus tinctorius*. The flowers are of a deep orange colour, but they are used for dyeing various shades of red. The flowers of the carthamus are employed in Spain for colouring dishes and confectionery. See SAFFLOWER.

DYER'S WOODHOOF, *Asperula tinctoria*. The roots of this plant are used in some parts of Europe, particularly Balmatia, instead of madder, for dyeing wool and cloth of a reddish colour; but in bulk the crop obtained is inferior to that of the madder. — *Lawson*.

E.

EARTHIS. (*Terres*, Fr.; *Erdlen*, Germ.) It has been demonstrated that the substances called Earths, and which, prior to the electro-chemical career of Davy, were deemed to be elementary bodies, are all compounds of certain metallic bases and oxygen. Five of the earths, when pure, possess decided alkaline properties, being more or less soluble in water, having (at least three of them) an acrid alkaline taste, changing the purple infusion of red cabbage to green, most readily saturating the acids, and affording thereby neutro-saline crystals; these are barytes, strontia, lime (calcium), magnesia, and lithia. The earths proper are alumina, glucina, yttria, zirconia, and thorium; these do not change the colour of infusion of cabbage or tincture of litmus, do not readily neutralise acidity, and are quite insoluble in water.

EARTHY COBALT. See WAD. A manganese ore, in which the oxide of cobalt sometimes amounts to thirty-three per cent. — *Dana*.

EARTHY MANGANESE. See WAD and MANGANESE.

EAST INDIA BLACK WOOD. The *Sit Sal* of the natives of India. *The Dalbergia latifolia*. It is a wood of a greenish black colour, with light coloured veins. It takes a fine polish, and is very heavy.

EAU DE COLOGNE. See PERFUMERY.

EAU DE LUCE. See PERFUMERY.

EBONY. Of this black wood three kinds are imported;—

The Mauritius Ebony, which is the blackest and finest grain.

The East Indian Ebony, which is not of so good a colour.

The African Ebony, which is porous and bad in point of colour.

The ebony of the Mauritius is yielded by the *Diospyros Ebenus*. Colonel Lloyd says, this ebony when first cut is beautifully sound, but that it splits like all other woods from neglectful exposure to the sun. The workmen who use it immerse it in water as soon as it is felled for from six to eighteen months; it is then taken out, and the two ends are secured from splitting by iron rings and wedges. Colonel Lloyd considers that next to the Mauritius, the ebony of Madagascar is the best, and next that of Ceylon.

The Mauritius ebony is imported in round sticks like scaffold poles, about fourteen inches in diameter. The East Indian variety comes to us in logs as large as twenty-eight inches diameter, and also in planks. The Cape of Good Hope ebony arrives in England in billets, and is called billet wood, about from three to six feet long, and two to four inches thick.

The uses of ebony are well known.

White Ebony comes from the Isle of France, and is much like box wood. See GREEN EBONY.

EBULLITION. (Eng. and Fr.; *Kochen*, Germ.) *Boiling*. When the bottom of an open vessel containing water is exposed to heat, the lowest stratum of fluid immediately expands, becomes therefore specifically lighter, and rises through the colder, and heavier particles. The heat is in this way diffused through the whole liquid

mass, not by simple communication of that power from particle to particle as in solids, —called the *conduction* of caloric,—but by a translation of the several particles from the bottom to the top, and the top to the bottom, in regular succession. This is denominated the *carrying power* of fluids, being common to both liquid and gaseous bodies. These internal movements may be rendered very conspicuous and instructive, by mingling a little powdered amber with water, contained in a tall glass cylinder, standing upon a sand-bath. That this molecular translation or locomotion is almost the sole mode in which fluids get heated, may be demonstrated by placing the middle of a pretty long glass tube, nearly filled with water, obliquely over an arched flame. The upper half of the liquid will soon boil, but the portion under the middle will continue cool, so that a lump of ice may remain for a considerable time at the bottom. When the heat is rapidly applied, the liquid is thrown into agitation, in consequence of elastic vapour being suddenly generated at the bottom of the vessel, and being as suddenly condensed at a little distance above it by the surrounding cold column. These alternate expansions and contractions of volume become more manifest as the liquid becomes hotter, and constitute the *summing*, vibratory sound which is the prelude of ebullition. The whole mass being now heated to a pitch compatible with its permanent elasticity, becomes turbulent and explosive under the continued influence of fire, and emitting more or less copious volumes of vapour, is said to boil. The further elevation of temperature, by the influence of caloric, becomes impossible in these circumstances with almost all liquids, because the vapour carries off from them as much heat in a latent state as they are capable of receiving from the fire.

The temperature at which liquids boil in the open air varies with the degree of atmospheric pressure, being higher as that is increased, and lower as it is diminished. Hence boiling water is colder by some degrees in an elevated situation, with a depressed barometer, than at the bottom of a coal pit in fine weather, or, when the barometer is elevated. A high column of liquid also, by resisting the discharge of the steam, raises the boiling point. As we ascend from the sea level, the boiling point becomes lower, the following table illustrates this.

	Yards high.	Inches of pressure.	Boiling point.
Farm of Antisana	4485	17.87	157.34
Quito	3170	20.74	194.18

Lyon	71	29.69	211.46

Notes

In *vacuo*, all liquids boil at a temperature about 124° F. lower than under the average atmospheric pressure. For a table of elasticities, see VACUUM. Gay Lussac has shown that liquids are converted into vapours more readily, or with less turbulence, when they are in contact with angular or irregular, than with smooth surfaces; that they therefore boil at a heat 2° F. lower in metallic than in glass vessels, probably owing to the greater polish of the latter. For example, if into water about to boil in a glass matrass, iron filings, ground glass, or any other insoluble powder be thrown, such a brisk ebullition will be instantly determined, as will sometimes throw the water out of the vessel; the temperature at the same time sinking two degrees F.

The following table exhibits the boiling heat, by Fahrenheit's scale, of the most important liquids:—

Ether	-	-	-	Graham	-	-	96°

EBULLITION ALCOHOLMETER. That the boiling temperature of water is increased by holding neutro-saline and saccharine substances in solution has been long known, and has been the subject of many experiments, made partly with the view of ascertaining from that temperature the proportion of the salt or sugar, and partly with the view of obtaining a practical liquid bath. But it seems to have been reserved for the Abbé Brossard-Vidal, of Toulon, to have discovered that the boiling temperature of alcoholic liquors is, in most cases, proportional to the quantity of alcohol, irrespectively of the quantity of neutro-saline or saccharine matter dissolved in them. When, however, such a quantity of dry carbonate of potash, or sugar, is added to a spirituous liquor as to abstract or fix, in the solid state, a portion of the water present, then the boiling temperature of that mixture will be lowered in proportion to the concentration of the alcohol, instead of being raised, as would be the case with water so mixed. But, generally speaking, it may be assumed as a fact, that the boiling point of an alcoholic liquor is not altered by a moderate addition of saline, saccharine, or extractive matter. On this principle, M. Brossard-Vidal constructed the instrument represented in fig. 684, for determining by that temperature the proportion of alcohol present. His chief object was to furnish the revenue boards of France with a means of estimating directly the proportion of alcohol in wines, so as to detect the too common practice of introducing brandy into their cities and towns under the mask of wine, and thereby committing a fraud upon the octroi; as the duty on spirit is much higher than on wine.

The above instrument consists of a spirit-lamp, surmounted by a small boiler, into which a large cylindric glass bulb is plunged, having an upright stem of such calibre that the quicksilver contained may, by its expansion and ascent when heated, raise before it a little glass float in the stem, which is connected by a thread with a similar glass bead, that hangs in the air. The thread passes round a pulley, which turning with the motion of the beads causes the index to move along the graduated circular scale. The numbers on this scale represent per cent. of absolute alcohol, so that

the number opposite to which the index stops, when the liquor in the cylinder over the lamp boils briskly, denotes the per centage of alcohol in it.
 Dr. Ure introduced another form of instrument (fig. 695). It is thus described by the inventor:—

It consists, 1, of a flat spirit-lamp A, surrounded by a snocoer for containing cold water to keep the lamp cool, should many experiments require to be made in succession; 2, of the boiler B, which fits by its bottom C, upon the cone of the lamp. At the point C, is seen the edge of the damper-plate for modifying the flame of the lamp, or extinguishing it when the experiment is completed. D is the thermometer, made with a very minute bar, in the manner of the bar. Mr. W. Hutton's instrument for measuring the height of a mountain by the boiling point of water on its summit. The bottom of the scale in the ebullition thermometer, is marked R for proof on the left side, and 100 (of proof spirit) on the right side. It corresponds to 178.6 Fahr. very nearly, or the boiling point of alcohol of 0.920 specific gravity. The following table gives the boiling points corresponding to the indicated densities.

Temp. Fahr.	Specific gravity.	Temp. Fahr.	Specific gravity.
178.6	0.9200 P.	185.6	0.9463 50 U. P.
179.75	0.9521 10 U. P.	190.0	0.9700 60 "
180.4	0.9420 20 "	191.8	0.9800 70 "
181.0	0.9510 30 "	196.4	1.0000 90 "
185.4	0.9600 40 "	202.0	0.920 90 "

The above table is the mean of a great many experiments. When alcohol is stronger than 0.92, or the excess proof, the boiling point varies too little with its progressive increase of strength to render that not applicable in practice. In fact, even for proof spirits, or spirits approaching in strength to proof, a more exact indication may be obtained by diluting them with their own bulk of water, before ascertaining their strength and then boiling it.

The boiling point of any alcohol liquor is apt to rise if the heat be long continued, and thereby to lead into error in using this instrument. This source of fallacy may be, in a great measure avoided by adding to the liquor in the little boiler above a teaspoonful (thirty-five grains) of common culinary salt, which has the curious effect of arresting the mercury in the thermometer at the true boiling point of the spirit,

wine, or beer, to enable a correct reading to be had. The small measure marked *x* holds the requisite quantity of salt.

The thermometer is at first adjusted to an atmospheric pressure of 29.5 inches. When that pressure is higher or lower, both water and alcohol boil at a somewhat higher or lower temperature. In order to correct the error which would hence arise in the indications of this instrument under different states of the weather, a barometrical equation is attached, by means of the subsidiary scale *x*, to the thermometer *n*.

Having stated the principles and the construction of the ebullition of the alcoholmeter, I shall now describe the mode of its application.

First.—Light the spirit lamp *a*.

Second.—Charge the boiling vessel *n*, with the liquid to be tested (to within an inch of the top), introducing at the same time a paper of the powder; then place the vessel *n* (the damper plate being withdrawn) on to the lamp *a*.

Third.—Fix the thermometer *n* on the stem attached to *n*, with its bulb immersed in the liquid. The process will then be in operation.

The barometrical scale indicated on the thermometer is opposite the mean boiling point of water. Prior to commencing operations for the day, charge the boiler *n* with water only, and fix the instrument as directed; when the water boils freely, the mercury will become stationary in the stem of the thermometer, opposite to the true barometrical indication at the time. Should the mercury stand at the line 29.5 this will be the height of the barometer, and no correction will be required; but should it stand at any other line, above or below, then the various boiling points will bear reference to that boiling point.

In testing spirituous or fermented liquors of any kind, when the mercury begins to rise out of the bulb of the thermometer into the stem, push the damper-plate half-way in its groove to moderate the heat of the flame. When the liquor boils freely the mercury will become stationary in the stem; and opposite to its indication, on the left, the underproof percentage of spirit may be read off at once, if the barometer stand that day at 29.5 inches; while on the right hand scale, the percentage of proof spirit is shown; being the difference of the former number from 100. The damper-plate is to be immediately pushed home to extinguish the flame.

The alcoholmeter will by itself only indicate the percentage of alcohol contained in any wine, but by the aid of the hydrometer, the proportionate quantity of saccharum in all wines may be readily and easily determined. The hydrometer will show the specific gravity of the liquid upon reference to table No. 1, annexed. In testing a sample of wine, first take the specific gravity, and suppose it to be 989, then charge the boiler of the alcoholmeter with the wine, as directed, and at the boiling point it indicates the presence of alcohol at 69.6 per cent.[°], whose specific gravity will be found to be 979; deduct that gravity from the gravity of the bulk, or 989, and 10 will remain, which 10 degrees of gravity, upon reference to the wine table, will be found to represent 25 lbs. of saccharine or extractive matter in every 100 gallons, combined with 30½ gallons of proof spirit.

Sikes's hydrometer will only show the sp. gr. of liquids lighter than water (or 1000), and for wines in general use, the gravities being lighter than that article, will answer every purpose; but there are wines whose gravities are heavier than water, such as mountain, tent, rich Malaga, hachryum (Christi, &c.), to embrace which additional weights to the hydrometer will be required, as for cordialised spirits, &c. In testing a sample of rich mountain, its sp. gr. was found to be 1039, or 32 degrees heavier than water; that wine at the boiling point indicated the alcohol 72.5 per cent.[°]; but 980 sp. gr. deducted from 1039 leaves 59 degrees of sp. gr.; against 59 of the wine tables will be found 147.5 or 147½ lbs. of saccharine or extractive matter, combined with 27½ gallons of proof spirit to every 100 gallons.

Should the barometer for the day show any other indication above or below the standard of 29.5, the thermometer scale will then only show the apparent strength, and reference must be had to the small ivory indicator, *x*, it being the counterpart of the barometrical scale of the thermometer; thus, should the barometer indicate 30, place 30 of the indicator against the boiling point of the liquid, and opposite the line of 29.5 will be found the true strength.

Example 1.—Barometer at 30.—Suppose the mercury to stop at the boiling-point 72.5, place 30 of the indicator against 72 on the thermometer, and the line of 29.5 will cut 49.6[°], the true strength.

Example 2.—Barometer at 29.—Suppose the mercury to stop at the same point, 72.5, place 29 of the indicator against 72 on the thermometer, and the line of 29.5 will cut 74.3[°], the true strength.

For malted liquors.—To all brewers and dealers in fermented liquors, this principle, by its application, will supply a great desideratum, as it will not only show the alcohol created in the wort by the attenuation, as well as the original weight of the wort prior

No. 1.

TABLE OF SPECIFIC GRAVITIES, by Sikes's Hydrometer, adapted to Field's Patent Alcoholmeter for Cordialized Spirits.

to fermentation, but it will indicate the value of malt liquors in relation to their component parts. It will likewise be a ready means of testing the relative value of worts from sugar compared with grain, as well as being a guide to the condition of stock beers and ales.

To ascertain the strength of malt liquors and their respective values, the instrument has been supplied with a glass saccharometer, testing-glass, and slide-rule. Commence by charging the testing-glass with the liquid, then insert the saccharometer, to ascertain its present gravity or density per barrel, and at whatever number it floats, that will indicate the number of pounds per barrel heavier than water.

Example 1.—Suppose the saccharometer to float at the figure 8, that would indicate 8 lbs. per barrel; then subtract the liquid to the boiling test, with the salt as before directed, and suppose it should show (the barometrical differences being accounted for) 90° F., that would be equivalent to 10 per cent. of proof alcohol. Refer to the slide rule.

and place *a* on the slide against 10 on the upper line of figures, and facing *a* on the lower line will be 12, thus showing that 12 lbs. per barrel have been decomposed to determine that percentage of spirit; then, by adding the 12 lbs. to the present 5 lbs. per barrel, the result will be 26 lbs., the original weight of the wort after leaving the copper.

Example 2—The saccharometer marks 16 lbs. per barrel, and at the boiling point it indicates 88° F. equivalent to 12 gallons of proof spirit per cent.; place *a* against 12, and opposite *n* will be 21½ lbs. per barrel, when, by adding it to the 10 lbs. present, 31½ lbs. will be the result.

To ascertain the relative value.—Suppose the price of the 26 lbs. of beer to be 7s. per barrel, and the 31½ lbs. beer to be 40s. per barrel, to ascertain which beer will be the cheapest place 26 on the opposite side of the rule against 36, and opposite 31½ lbs. will be 43s. 7d., showing that the latter beer is the cheapest by 3s. 7d. per barrel.

By taking an account of the malt liquors by this instrument prior to stocking, it may be ascertained at any time whether any alteration has taken place in their condition, either by an increase of spirit by after fermentation and consequent loss of saccharum, or whether, by an apparent loss of both, acetous fermentation has not been going on towards the ultimate loss of the whole.

This instrument will likewise truly indicate the quantity of spirit per cent. created in distillers' worts, whether in process of fermentation or ready for the still; the only difference will be in the allowances on the slide-rule.

N.B.—The saccharometers applicable to the foregoing rules for beer, ale, &c., have been adjusted at the temperature of 60° Fahrenheit, and will be found correct for general purposes; but where extreme minuteness is required, the variation of temperature must be taken into account; therefore for every 10 degrees of temperature above 60, 1/16th of a pound must be added to the gross amount found by the slide-rule; on the contrary, for every 10 degrees below 60, 1/16th of a pound must be deducted.

For cordialised Spirits.—The operation in this instance is somewhat different from that of beers, which have the alcohol created in the original worts; whereas, in cordialised spirits, gins, &c., the alcohol is the original, and the saccharine matter, or sugar, is an addendum.

If 100 gallons of spirits are required at a given strength, any 50 per cent. under proof, 50 gallons of proof spirit, with the addition of fifty gallons of water, would effect that object, and upon testing it by the alcoholmeter, it would be found as correct as by the hydrometer. But in cordialising spirits it is different, for to the 50 gallons of proof spirit 50 gallons of sugar and water would be added, thereby rendering the hydrometer useless, except for taking the specific gravity of the bulk, and according to the quantity of sugar present, as a relative quantity of water must have been displaced; and as the sugar has no reducing properties, the alcoholmeter will only show the strength of the cordial in relation to the water contained in it, as the principle indicates, respectively of saccharine or extractive matter present.

Suppose, in making 100 gallons of cordial at 50° F., 31½ lbs. of sugar are put to 50 gallon, or 300 lbs. to the 100 gallons, that 300 lbs. of sugar, 150½ gallons of water, only 31½ gallons of water instead of 50 have been applied; the sugar, with its reducing properties, making up the bulk of 100 gallons, which is meant to represent 50 per cent. °F.

The alcoholmeter will only show at the full point of ebullition the alcoholic strength in relation to the water in the 100 gallons of the mixture, or 55 per cent. °F., leaving 13 per cent. to be accounted for on the bulk.

As the quantity of sugar present must be determined before that percentage can be arrived at, a double object will be effected by so doing, namely, showing in all instances the quantity of sugar present, as well as the percentage of spirit to be accounted for.

Example 1.—In taking the sp. gr. of a cordial, suppose it to be found 1076, then submit the liquid to the boiling point, and having ascertained the percentage of alcohol, and it proves to be 33° F., the sp. gr. of alcohol at that strength will be found to be 936; deduct 936 from the sp. gr. of the bulk, or 1076, and 140 will remain; refer that to its amount on the head line of the table No. 2, namely, 140, under which will be found 3, representing 3 lbs. of sugar to the gallon; and by running the eye down its column to opposite the alcoholic strength indicated (33° F.) will be found 119, which represents the percentage of water displaced by the sugar, and which amount of 119, added to the 55 per cent. ascertained, makes the total upon the bulk 49½ per cent. °F., with 3 lbs. of sugar to the gallon.

For Gins, &c.—Example 2. In taking the sp. gr., suppose it to be found 937; then submit to the boiling point, and it proves to be 11° F., where sp. gr. is 917, which deducted from 937, leaves sp. gr. 20; on the head line of table No. 2, under 20, will be found 8½ oz., or ½ lb. of sugar to the gallon, and on running the eye down its opposite

14° F. will be found 3.0, which added to the 14, makes the total on the bulk 17 per cent. ° F., with 50 lbs. of sugar to the 100 gallons.

To chemists for their tinctures, &c., this instrument will be found essentially useful.

N.B.—Care must be taken that the mercury is entirely in the bulb of the thermometer before it is fixed on the stem for operation, and in all cases (except for water) the salt must be used.

EDGE TOOLS; more properly *cutting tools*, of which the chisel may be regarded as the type. Houtzappel, whose book on *Mechanical Manipulation* is the best to be found in any language, divides cutting tools into three groups, — namely paring tools, scraping tools, and shearing tools.

First. Paring or splitting tools, with thin edges, the angles of which do not exceed sixty degrees; one plane of the edge being nearly coincident with the plane of the work produced (or with the tangent in circular work). These tools remove the fibres principally in the direction of their length, or longitudinally, and they produce large coarse chips, or shavings, by acting like the common wedge applied to mechanical power.

Secondly. Scraping tools, with thick edges, that measure from sixty to one hundred and twenty degrees. The planes of the edges form nearly equal angles with the surface produced, or else the one plane is nearly or quite perpendicular to the face of the work (or becomes as a radius to the circle). These tools remove the fibres in all directions with nearly equal facility, and they produce fine dust-like shavings by acting superficially.

Thirdly. Shearing, or separating tools, with edges of from sixty to ninety degrees generally duplex, and then applied on opposite sides of the substances. One plane of each tool, or of the single tool, coincident with the plane produced.

Mr. James Honydell introduced a process which professes to produce cheap edge tools of excellent quality. We believe the result has not been so satisfactory as the patentee expected. He welds iron and steel together in such a manner that when cut up to form edge tools, the steel will constitute a thin layer to form the cutting edge. He piles a slab or plate of steel upon two or more similar plates of iron, heats in a furnace to a good welding heat, and then passes between grooved or other suitable rollers, to convert it into bars; the steel being in a thin layer either on one of the outer surfaces of the bar, or between two surfaces of iron according to the kind of tool to be made therefrom. The bars thus produced are cut up and manufactured into the shape of the desired articles by forging. If the cutting edge is to extend but a short distance, the steel is applied only near one edge of the pile. The compound bars which have the steel on one side are suitable for chisels and other tools, which have a cutting edge on one side, the iron being ground away when making or sharpening the tool. See CUTLERY; STEEL.

EDULCORATE (*Edulcorer*, Fr.; *Aussüßen*, Germ.) is a word introduced by the alchemists to signify the sweetening, or rather rendering insipid, of acrimonious pulverulent substances, by copious ablutions with water. It means, in modern language, the washing away of all particles soluble in water, by agitation or trituration with this fluid, and subsequent decantation or filtration.

EFFERVESCENCE. (Eng. and Fr.; *Aufschäumen*, Germ.) When gaseous matter is suddenly extricated with a hissing sound during a chemical mixture, or by the application of a chemical solvent to a solid, the phenomenon, from its resemblance to that of simmering or boiling water, is called effervescence. The most familiar example is afforded in the solution of sodic powders; in which the carbonic acid gas of bicarbonate of soda is extricated by the action of citric or tartaric acid.

EFFLORESCENCE (Eng. and Fr.; *Verwittern*, Germ.) is the spontaneous conversion of a solid, usually crystalline, into a powder, in consequence either of the abstraction of the combined water by the air, as happens to the crystals of sulphate and carbonate of soda; or by the absorption of oxygen and the formation of a saline compound, as in the case of alum schist, and iron pyrites. Saltpetre appears as an efflorescence upon the ground and walls in many situations.

EGGS, HATCHING. See INCUBATION, ARTIFICIAL.

ELDER-DOWN is so called because it is obtained from the *Elder-duck*. These birds build their nests among precipitous rocks, and the female lines them with fine feathers plucked from her breast, among which she lays her five eggs. The natives of the districts frequented by the elder-ducks let themselves down by cords among the dangerous cliffs, to collect the down from the nests. It is used to fill coverlets, pillows, cushions, &c.

ELAINE (called also *OLIXIR*) is the name given by Chevreul to the thin oil, which may be expelled from tallow and other fats, solid or fluid, by pressure either in their natural state or after being saponified, so as to harden the *stearine*. It may be extracted also by digesting the fat in seven or eight times its weight of boiling alcohol, spec. grav.

799, till it dissolves the whole. Upon cooling the solution, the stearine falls to the bottom, while the elaine collects in a layer like olive oil, upon the surface of the supernatant solution, reduced by evaporation to one eighth of its bulk. If this elaine be now exposed to a cold temperature, it will deposit its remaining stearine, and become pure. Bracconot obtained it by exposing olive oil to a temperature of about 21° F. in order to cause the congelation of the margarine or stearine (?). The elaine was a greenish yellow liquid; at 14° F. it deposited a little margarine. See OILS and STEARINE.

ELASTIC BANDS. (*Tannus elastiques*, Fr.; *Elastische Bänder*, Germ.) See CAOUTCHOUK and BRAIDING MACHINE.

ELASTICITY. The property which bodies possess of occupying, and tending to occupy, portions of space of determinate volume, or determinate volume and figure, at given pressures and temperatures, and which, in a homogeneous body, manifests itself equally in every part of appreciable magnitude (*Nicht*). The examination of this important subject in KINETICS does not belong to this work. A few remarks, and some explanations, only are necessary.

Elastic Pressure is the force exerted between two bodies at their surface of contact.

Compression is measured by the diminution of volume which the compressible (elastic) body undergoes.

The *Modulus or Coefficient of Elasticity* of a liquid is the ratio of a pressure applied to, and exerted by, the liquid to the accompanying compression, and is therefore the reciprocal of the compressibility. The quantity to which the term *Modulus of Elasticity* was first applied by Sir, Young, is the reciprocal of the extensibility or longitudinal pliability. (See the Edinburgh Transactions, and those of the Royal Society, for the papers of Barlow, Maxwell, and Rankine, and the British Association Reports for those of Fairbairn, Hodgkinson, &c.)

Various tables, showing the elasticity of metals, glass, &c., have been constructed, and will be found in treatises on mechanics. The following notices of the mechanical properties of woods may prove of considerable interest. The experiments were by Chevaudier and Wertheim.

Rods of square section 10 mm in thickness and 2 m in length were prepared, being cut in the direction of the fibres, and the velocity of sound in them was determined by the longitudinal vibrations, their elasticity from their increase in length, and their cohesion by loading them to the point of rupture. Small rods were cut in planes perpendicular to the fibre grain (in directions radial and tangential to the rings of growth) and their elasticity and sound velocity were measured by the lateral vibrations. It was thus again established, that the coefficients of elasticity, as deduced from the vibrations, come out higher than those derived from the elongation.

Names of the woods	Density	Sound velocity			Coefficients of elasticity			Cohesion.

l. refers to rods cut lengthwise with the grain.
R to those cut in a direction radial, and
T to those tangential to the annual rings.

ELATERIUM. A peculiar extract obtained from the juice of the wild cucumber. (*Momordica elaterium*).

ELDEN. (*Sambucus nigra*, Surcou, Fr.; *H. Munder*, Germ.) Pith balls for electrical purposes are manufactured from the pith of the elder tree, dried. The wood is employed for inferior turnery work, for weaver's shuttles, netting pins, and shoemakers' pegs. Its elasticity and strength render it peculiarly fitted for these latter purposes.

ELECTIVE AFFINITY. (*Wahlverwandtschaft*, Germ.) See DECOMPOSITION.

EQUIVALENTS.

ELECTRIC CLOCKS. The application of electricity as a motive power to clocks, and as a means of transmitting synchronous signals or time, is naturally inter-

mately connected with the attempts (not yet realised in an economic point) to apply it as a motive power to machinery, and with its application, so fully realised (see article ELECTRO-TELEGRAPHY), to telegraphy proper; and it has grown up side by side with the latter. Prof. Wheatstone's attention was directed to it in the very early days of telegraphy. Without entering upon the history of electric clocks, it will suffice to describe two principles on which they have been constructed, and which are best known, — Bain's and Shepherd's. In the former, electricity maintains the pendulum in motion, and the pendulum drives the clock-train; in the latter, the motion of the pendulum is maintained by electricity, but the clock-train is driven by distinct currents, sent to it by means of pendulum contacts.

The bob of Bain's pendulum consists of a coil of wire, wound on a bobbin with a hollow centre. The axis of the bobbin is horizontal. Bar magnets, presenting similar poles, are fixed on each side of the coil, in such a position that, as the pendulum oscillates right and left, the poles on either side may enter the coil of wire. It is one of the laws of electric currents, when circulating in a helix, or spiral, or coil, or even in a single ring, that each face of the coil presents the characters of a magnetic pole, of a south pole if the current circulates in the direction in which the hands of a watch move, of a north pole, if it circulates in the reverse direction. Things are so arranged in Bain's pendulum that a battery current is alternately circulating in and cut off from the coil. When the current is circulating, the coil has the character of a

magnet, with a north end and a south end; if the permanent magnets present north poles, the north end of the coil bob will be repelled from one of the magnets, while its south end will be attracted by the other magnet. This constitutes the impulse or maintaining power in one direction. Now the connections are such that, when the arc of vibration is complete and the pendulum ready for the return vibration, the pendulum rod pushes aside a golden slide, by which the electric circuit had been completed, and the current is cut off; the pendulum is thus able to make its return vibration by mere gravity. It starts to repeat the above operations by mere gravity; but, ere it completes the arc, the rod pushes back the slide, and again completes the electric circuit, and gives rise to a second impulse, and so on. A small amount of magnetic attraction is sufficient to supply the necessary amount of maintaining power. One pair of zinc-copper, buried in the moist earth, has been found ample.

In an ordinary clock, the train is carried by a weight or by a spring, and the time is regulated by the pendulum. In Bain's the time is regulated and the train is driven by the pendulum. The rod hangs within a crutch in the usual way, the crutch carries pulleys of a particular kind, set in a groove wheel; and from the latter, the motion is transmitted to a train of the usual character; but much lighter. For large clocks, Mr. Bain proposes a modification of the slide, which shall invert the current at each oscillation, so as to have attraction as a maintaining power in both oscillations. The general arrangement of the pendulum is shown in *fig 646*. *n* is the pendulum bob, with its coil of wire, the ends of which pass up on either side of the rod. *a* and *c* are the battery plates, with their attaching wires *p* and *p'*. The arrows show the course of the voltaic current from the plate *c* by the wire *p'*, thence down the pendulum rod by the right hand wire, through the coil *n*, up by the wire on left side of rod, then by the wire *c*, along the slide at *x*, and by the

wire *p* to the zinc plate *z*. When the slide *x* is in position, the circuit is complete, and the bob is attracted by the *a* pole of one of the magnets, and repelled by the *c*

point of the other. When the slide is displaced, the attraction ceases, and the pendulum is left to the mere action of gravity.

Shepherd's electric clock has a remontoir escapement. There is no direct connection between the electric force and the pendulum, or between the pendulum and the clock train. The attractive power, derived from the electric current, is simply employed to raise the same small weight to the same height; and the clock-train is carried by the attractive force derived from electric currents, whose circuits are completed by the pendulum touching contact springs. The pendulum is thus protected from the influence of change in the force of the current, or from irregular resistances in the train. *Fig. 687* is a perspective view of this pendulum, with batteries, &c.

687

attached, and the clock connections and those of its batteries, *s z z*, shown. The electricity leaves the pendulum battery by the wire *a*, and returns to it by the wire *r*.

There is only one break in this circuit, namely, at *k*, which is a slender spring faced with platinum, that is in contact with platinum on the pendulum at the extreme of its right vibration, but at no other time. The wire *a* reaches the pendulum from the battery by the coils *n*, the plate *c*, and the frame *v*; the wire *r* goes direct from the spring *k* to the zinc *z*. From this arrangement, it happens that every time the contact at *k* is completed, the iron core, of which the ends *n* *a* are visible, contained within the coils *n*, becomes a magnet, and when the contact at *n* is broken, the magnetism ceases. The poles *n* *a* have, therefore, a power alternately to attract and to release *a*, which is a plate or armature of soft iron, moving on an axis, as shown in the figure, and to which is attached a bar *b*, with a counterpoise *i*. We have said that the office here of the electric force, is merely to raise a weight; the fall of the weight maintains the pendulum in motion. When the armature *a* is attracted, the lever *b* is raised; this raises the wire *c* into a horizontal position, and its other part *d* into a vertical position; the latter is caught and retained by the latch or detent *e*; so that when the magnetic attraction ceases, the counterpoise *i* descends with the lever *b*; and so the armature *a* leaves the electro-magnet *n* *a*. But the wire *d* remains vertical, and its other part with the small weight *r* remains horizontal. Now, when the pendulum makes its left hand oscillation, the point of the screw *f* impinges upon the stem *g*, and carries it a little to the left; this raises the detent *e*, and liberates the piece *d* *c*, which descends into its original position by gravity; the small ball *c* adds to its weight. In descending, the vertical piece *c* strikes against the point of the screw *h*, and gives a small impulse to the pendulum *p*. The ball *c* is not larger than a pea, and its fall is not an eighth of an inch; but the impact is sufficient to keep the pendulum in motion; and it is constant, being this same body falling through the same space; and is independent of any variation in the battery power, which latter is only concerned in raising the ball. The arc of the pendulum's vibration is regulated by adjusting the small ball to a greater or less distance from the centre. Provision is thus made for maintaining the pendulum in motion, and giving it an impact of constant value. If this arrangement is in connection with a compensating mercurial pendulum, extreme accuracy of time-keeping is attained. The next step is to transfer the seconds, thus secured, to a dial or clock. The same movement of the keeper *a* with its counterpoise *i*, has sometimes been made to impart motion to the seconds wheel of a clock train; but more commonly the clock train is distinct, as shown in the drawing, and is carried by a special electro-magnetic arrangement, in connection with separate batteries, *s* *c*, *s* *c*, the contacts of which are, however, under the control of the pendulum. Insulated springs, *k* and *l*, are fixed near the top of the rod; from *k* a wire leads to the silver *s*, of the left hand battery; and from *l* another wire leads to the zinc *z*, of the right hand battery. The other metals of the respective batteries are connected by a wire with an electro-magnet within the clock, the other end of the said electro-magnet being connected with the metal bed and frame of the pendulum. When, therefore, the pendulum oscillates to the right, the circuit is completed at *k*; and the current of the left hand battery circulates from *s* through the wire *k*; and thence through the metal frame and by the wire to the clock, and so to the zinc *z*. When the oscillation is to the left and *l* is in contact, the right hand battery is in action; and the current circulates from *s* through the clock, to the metal frame, and thence to *l* and to the zinc *z* of the battery. In one case, a voltaic current enters the clock by the wire shown below, and leaves it by the upper wire; and, in the other case, it enters by the upper and leaves by the lower wire. There is a double set of electro-magnets within the clock, showing four poles in all; there are also two magnetised steel bars, mounted see-saw fashion, with their poles alternate, and facing the four electro-magnetic poles. When the current enters the clock from below or in one direction, the bars oscillate this way; when it enters from above or in the reverse direction, they oscillate that way. They are both fixed at right angles to and upon the same axis; which axis carries a pair of driving pallets, that act on a scape-wheel, and so the clock-train is driven. It will be seen at a glance, that two or more clocks may be connected in the same circuit, as readily as one; it being merely necessary in such case to modify the battery power, to correspond with the work to be done. For instance, three such clocks have been going for several years at Tonbridge by the same pendulum; several are actuated in like manner at the Royal Observatory, Greenwich. Nor is it necessary that the clocks should be in the same room with the pendulum, or in the same building, or even in the same parish. All the clocks above referred to, are variously distributed; and one of the Observatory clocks is six miles distant from its pendulum, being at the London Bridge Station of the South-Eastern Railway.

In cases where it has not been found convenient to drive the clock train, especially in the case of a public one, the movement of which is heavy, great advantage has been derived for regulating the oscillations of the pendulum of the large clock, by means of electric currents, under the control of a standard pendulum. Mr. Jones

has adopted this method, and it is likely to meet with much favour. The turret clock, under this arrangement, is driven by weights in the usual way, and the time is regulated by a pendulum. The bob of the pendulum is placed under a condition analogous to that of Bain's (fig. 686), the permanent magnet, however, being attached to the pendulum, and the electro-magnet fixed facing it. If currents are made to circulate synchronously in the latter, by means of a standard pendulum, the oscillations of the pendulum of the turret-clock are constrained to accord with those of the standard, and a very perfect system of time-keeping is obtained. This is practised at Liverpool; and has just been introduced at Greenwich.

Under the above arrangements the clock is controlled by the standard pendulum second by second, and the two keep time together throughout the day. There are cases in which it is sufficient, and also more convenient, to correct a clock once a day only by means of a telegraph signal transmitted from a standard clock. This is managed in several ways. There is a clock at the Telegraph Office in the Strand; a good regulator, adjusted to gain a second or two during the twenty-four hours, and to stop at 1 P.M. A telegraph signal is sent from the Royal Observatory precisely at one, that drops a time-ball at the Strand office, which, in falling, starts the clock. At Ashford, seventy-three miles from Greenwich, there is an electric clock which has a gaining rate, and which is so constructed that the battery circuit is opened at one o'clock by means of pins and springs attached to the movement, and the clock therefore stops. At 1 P.M., Greenwich mean time, a signal is sent through the Ashford clock from the Royal Observatory, which starts it at once at true time. At the Post office, Lombard Street, there is a clock which, in the course of the twenty-four hours, raises a weight. At noon a telegraph signal is sent from Greenwich, which passes through an electro-magnet; the latter attracts an armature of soft iron and liberates the ball, which falls, and in falling it encounters a crutch, or lever, attached to the second's hand, and thrusts it this way or that, as the case may be; but so as to bring it to sixty seconds on the dial, and thus to set the clock right.

Intermediate between the one method of sending a signal every second to regulate a clock, and the other method of sending it once an hour, we have the following arrangement of Bain's for sending it once an hour. Fig. 688 shows the arrangement, with part of the dial removed, to show the position of the electro-magnet. The armature is below; it carries a vertical stem, terminating above in a fork. Its ordinary position is shown by the dotted lines. The minute hand (partly removed from the cut) carries a pin on its back surface. When the hand is near to sixty minutes, and an electric current is sent through the magnet, the armature is attracted upwards and the fork takes the position shown by the full lines at the top of the dial, and, in doing so, it encounters the pin and forces the hand into the vertical position, and sets the clock to true time, providing the signal comes from a standard clock, or is sent by hand at true time. A dial of moderate character keeps so near to time, that once or twice a day would be, for all common purposes, often enough to correct it.

Fig. 689 is an arrangement of Bain's, by which a principal clock, showing seconds, sends electric currents at minute intervals to other clocks, and causes the hand to move minute by minute. *A* is a voltaic battery; *n* is the principal clock, which may be an electric clock or not at pleasure; *o* and *u* are two out of many subordinate clocks. The seconds hand of the principal clock completes a voltaic circuit twice (for the case of two clocks) during the minute; at the 30 seconds for the clock *o*, and at the 60 seconds for the clock *u*. The clock *u* shows time in leaps from one minute to the next; and the clock *o* from one half minute to the next half minute. As many more contacts per minute may be provided for the seconds hand of the prime clock as there are subordinate clocks.

Next akin to the time signals above described, and which act automatically upon clocks, either to drive the clock-train or to correct the clock errors, are mere time signals, which are extensively distributed throughout the country by the ordinary telegraph wires, and are looked for at the various telegraph stations, in order to compare the office dials with Greenwich mean time, and to make the necessary correction; they are also re-distributed by hand the moment they appear, through sub-districts branching from junction stations. Large black balls, housed in conspicuous stations,

are also dropped daily by electric currents in various places, for the general information of the public, or of the captains of ships.—C. V. W.

ELECTRICITY for Blasting in Mines and Quarries. Professor Hare was the first who entertained this idea, but Mr. Martin Roberts devised the following process. In order not to be called upon to make afresh a new apparatus for each explosion, Mr. Roberts invented cartridges, which may be constructed beforehand. With this view, two copper wires are procured, about a tenth of an inch in diameter, and three yards in length, well covered with silk or cotton tarred, so that their insulation may be very good. They are twisted together (Fig. 690) for a length of six inches, care being taken to leave their lower extremities free, for a length of about half an inch (separating them about half an inch), from which the insulating envelope is removed, in order to stretch between them a fine iron wire, after having taken the precaution of cleaning them well. The upper extremities of the two copper wires are likewise separated, in order to allow of their being placed respectively in communication with the conductors, that abut upon the poles of a pile. The body of the cartridges is a tin tube, three inches long, and three quarters of an inch in diameter, the solderings of which are very well made, in order that it may be perfectly impermeable to water. A glass tube might equally well be employed, were it not for its fragility, which has caused a tin tube to be preferred. The system of copper wires is introduced into the tube, fixing them by means of a stem that traverses it at such a height that the fine iron wire is situated in the middle of the tin tube, so arranged that the ends of the copper wire do not anywhere touch the sides of the tube (Fig. 691). The cork is firmly fixed at the upper extremity of the tube with a good cement. Mr. Roberts recommends for this operation, a cement composed of one part of bees-wax and two parts of resin; the tube is then filled with powder by its other extremity, which is likewise stopped with a cork, which is cemented in the same manner. Figure 692 indicates the manner in which the cartridge is placed in the hole, after having carefully expelled all dust and molature; care must be taken that the cartridge is situated in the middle of the charge of powder that is introduced into the hole. Above the powder is placed a plug of straw or tow, so as to allow between it and the powder a small space filled with air; and above the plug is poured dry sand, until the hole is filled with it. The two ends of the copper wires that come out of the cartridge are made to communicate with the poles of the pile, by means of conductors of sufficient length, that one may be protected from all dangers arising from the explosion of the mine.

M. Rahmikorff, and after him, M. Verdu, have successfully tried to substitute the induction spark for the incandescence of a wire, in order to bring about the ignition of the powder. This process, besides the considerable economy that it presents—since instead of from fifteen to twenty Bunsen's pairs, necessary for causing the ignition

of the wire, it requires but a single one for producing the induction spark. — possesses the advantages of being less susceptible of derangement. Only it was necessary to

contrive a plan to bring about the ignition of the powder; in fact, it happens, that when by the effect of the length of the conductors that about upon the mine, the circuit presents too great a resistance, the induction spark is able to pass through the powder without inflaming it. M. Ruhmkorff has conceived the happy idea of seeking for a medium, which, more easily inflammable by the spark, may bring about the ignition of the powder in all possible conditions. He found it in Statham's fuses, which are prepared by taking two ends of copper wire covered with ordinary gutta percha; they are twisted (fig. 693), and the ends are bent so as to make them enter into an envelope of vulcanized (sulphured) gutta percha, which has been cut and drawn off from a copper wire that had been for a long time covered with it. Upon this envelope a sloping cut *a, b*, is formed; and after having maintained the extremities of the copper wires at about the eighth of an inch from each other, their points are covered with fulminate of mercury, in order to render the ignition of the powder more easy. The cut is filled with powder, and the whole is wrapped round with a piece of caoutchouc tube, *c, d*, or else it is placed in a cartridge filled with powder.

In the Statham fuses, it is the sulphide (sulphur t) of copper adhering to the wire, produced by the action of the vulcanized gutta percha which is removed from the copper wire that it covered, which by being inflamed under the action of the induction spark brings about an explosion. But it is necessary to take care when the fuse has been prepared, as we have pointed out, to try it in order to regulate the extent of the solution of continuity. It might, in fact, happen that while still belonging to the same envelope of a copper wire, the sheath of a vulcanized gutta percha with which the fuse is furnished, may be more or less impregnated with sulphide of copper; now, if the sulphide of copper is in too great quantity, it becomes too good a conductor, and prevents the spark being produced; if, on the contrary, it is not in a sufficiently large quantity, it does not sufficiently facilitate the discharge.

The first trials on a large scale of the application of the process that we just described, were made with Ruhmkorff's induction apparatus, by the Spanish colonel, Verdu, in the workshops of M. Herkman, manufacturer of gutta percha covered wire, at la Villette, near Paris. Experiments were made successively upon lengths of wire of 400, 600, 1000, 3000, and up to 26,000 metres (of 320 feet); and the success was always complete, whether with a circuit composed of two wires, or replacing one of the wires by the earth; two ordinary Daniell's pairs were sufficient for producing the induction spark with Ruhmkorff's apparatus. Since his first researches with M. Ruhmkorff, M. Verdu has applied himself to fresh researches in Spain; and he was satisfied, by many trials, that of all explosive substances, not any one was nearly so sensitive as fulminate of mercury; only, in order to avoid the danger that arises from the facility of explosion of this compound, he takes the precaution of introducing the extremity of the fuses into a small gutta percha tube, closed at the end. After having filled with powder this species of little box, and having closed it

hermetically, the fuses may be carried about, may be handled, may be allowed to fall, and even squeezed rather hard, without danger. The elastic and leather-like nature of gutta serena, which has been carefully softened a little at the fire, preserves the fulminate from all chance of accident. We may add, that with a simple Bunsen's pair, and by means of Ruhmkorff's induction apparatus, M. Verdu has succeeded in producing the simultaneous explosion of six small mines, interposed in the same circuit at 320 yards from the apparatus. He has not been beyond this limit; but he has sought for the means of acting indirectly upon a great number of mines, by distributing them into groups of five, and by interposing each of these groups in a special circuit. The fuses of each group are made to communicate by a single wire, one of the extremities of which is buried in the ground, and whose other extremity is near to the apparatus. On touching the induction apparatus successively with each of the free ends that are held in the hand, which requires scarcely a second of time, if there are four wires, that is to say, four groups and consequently twenty mines, twenty explosions are obtained simultaneously at considerable distances. There are no limits either to the distance at which the explosion may take place, or to the number of mines that may thus be made to explode.

ELECTRIC LIGHT. Various attempts have been made, from time to time, to employ electricity as an illuminating power; but hitherto without the desired success. The voltaic battery has been employed as the source of electricity, and in nearly all the arrangements, the beautiful arc of light produced between the poles, from the points of the hardest charcoal, has been the illuminating source. One of the great difficulties in applying this agent arises from the circumstance that there is a transference of the charcoal from one pole to the other, and consequently an alteration in the distance between them. This gives rise to considerable variations in the intensity and colour of the light, and great want of steadiness. Various arrangements, many of them exceedingly ingenious, have been devised to overcome these difficulties.

The most simple of the apparatus which has been devised is that of Mr. Staiter, which has been modified by M. Arclereau. Two metal columns or stems, to which any desired form can be given, are connected together by three cross pieces, so as to form one solid frame; one of these cross pieces is metallic, it is the one which occupies the upper part of the apparatus; the others must be of wood. These latter serve as supports and points of attachment to a long bobbin placed parallel to the two columns and between them, and which must be made of tolerably thick wire, in order that the current, in traversing it without melting it, may set upon a soft iron rod placed in the interior of the bobbin. This iron rod is soldered in a brass stem of the same calibre, and of the same length, carrying at its free extremity a small pulley. On the opposite side the iron carries a small brass tube, with sliding screws, into which is introduced one of the carbons, when the entire rod has been placed in the interior of the bobbin. Then a cord fixed to the lower cross piece, and passing over a pulley of large diameter, is able to serve as a support to the movable iron rod, running in the groove of the little pulley. For this purpose, it only requires that a counterpoise placed at the end of the cord shall be enabled to be in equilibrium with it. The metal cross piece which occupies the upper part of the apparatus, carries a small brass tube, which descends perpendicularly in front of the carbon that is carried by the electro-magnetic stem, and into which is also introduced a carbon crayon. By means of a very simple adjustment, this tube may besides be easily regulated, both for its height and for its direction; and consequently the two carbons may be placed very exactly above one another. The apparatus being adjusted, we place one of the two metal columns of the apparatus in connection with one of the poles of the pile, and cause the other pole to abut upon the copper wire of the bobbin (one end of which is soldered upon its socket). The current then passes from the bobbin to the lower carbon by the rod itself that supports it, and passing over the interval separating the two carbons, it arrives at the other pole of the pile by the upper cross piece of the apparatus and the metal column, to which one of the conducting wires is attached.

So long as the current is passing and producing light, the bobbin reacts upon the iron of the electro-magnet rod, which carries the lower carbon and attracts it on account of the magnetic reaction that solenoids exercise over a movable iron in their interior. It is this which gives to the carbons a separation sufficient for the luminous effect.

But immediately the current ceases to pass, or is weakened, in consequence of the consumption of the carbons, this attraction ceases, and the movable carbon, acted on by the counterpoise, is found to be drawn on and raised until the current passes again; equilibrium is again established between the two forces, and the carbons may be employed again. Thus, in proportion as the light tends to decrease, the counterpoise reacts; and this it is that always maintains the intensity of the light equal.

M. Breton has an apparatus which differs somewhat from the above, and M. Foucault has also devised a very ingenious modification.

M. Duboscq has made by far the most successful arrangement, for a description of which we are indebted to *De la Rue's Treatise on Electricity*, translated by C. V. Walker. The two carbons, between which the light is developed, burn in contact with the air, and shorten at each instant; a mechanism is consequently necessary, which brings them near to each other, proportionally to the progress of the combustion;

694

and since the positive carbon suffers a more rapid combustion than the negative, it must travel more rapidly in face of this latter; and this in a relation which varies with the thickness and the nature of the carbon. The mechanism must satisfy all these exigencies. The two carbons are unceasingly solicited towards each other, the lower carbon by a spiral spring, that causes it to rise, and the upper carbon by its weight, which causes it to descend. The same axis is common to them.

The galvanic current is produced by a Bunsen's pile of from 40 to 50 elements:

it arrives at the two carbons, as in apparatus already known, passing through a hollow electro-magnet, concealed in the column of the instrument. When the two carbons are in contact, the circuit is closed, the electro-magnet attracts a soft iron, placed at the extremity of a lever, which is in gear with an endless screw. An antagonistic spring tends always to unwind the screw as soon as a separation is produced between the two carbons; if it is a little considerable, the current no longer passes, the action of the spring becomes predominant, the screw is unwound and the carbons approach each other until the current, again commencing to pass between the two carbons, the motion that drew them towards each other is relaxed in proportion to the return of the predominance of the electricity over the spring; the combination of the carbons again increases their distance, and with it the superior action of the spring; hence follows again the predominance of the spring, and so on. These are alternatives of action and reaction, in which at one time the spring, at another time the electricity, has the predominance. On an axis, common to the two carbons, are two pulleys: one, the diameter of which may be varied at pleasure, communicates by a cord with the rod that carries the lower carbon, which corresponds with the positive pole of the pile; the other, of invariable diameter, is in connection with the upper or negative carbon. The diameter of the pulley, capable of varying proportionally to the using of the carbon, with which it is in communication, may be increased from three to five. The object of this arrangement is to preserve the luminous point at a convenient level, whatever may be the thickness or the nature of the carbons. It is only necessary to know that at each change of kind or volume of the carbon, the diameter of the pulley must be made to vary. This variation results from that of a movable drum, communicating with six levers, articulated near the centre of the sphere; the movable extremity of the six arms of the lever carries a small pin, which slides in cylindrical slots. These slots are oblique in respect of the sphere; they form inclined planes. A spiral spring always rests upon the extremity of the levers; so that, if the inclined planes are turned towards the right, the six levers bend towards the centre, and diminish the diameter. If, on the contrary, they are turned towards the left, the diameter increases, and with it the velocity of the translation of the carbon, which communicates with the pulley. We may notice, in passing, that this apparatus is marvellously adapted to the production of all the experiments of optics, even the most delicate; and that, in this respect, it advantageously supplies the place of solar light. As it is quite impossible to describe accurately the minute-arrangements of this instrument, the letters of reference have not been used in the text.

Dr. Richardson informs us, that although Mr. Grove calculated, some years ago, that for acid, zinc, wear and tear, &c. of batteries, a light equal to 1444 wax candles could be obtained for about 3s. 6d. per hour, the cost of the light employed for about five minutes at Her Majesty's Theatre, as an incident in the ballet, which was obtained by employing 75 cells of Callan's battery of the largest size, was said to be 2l. per night, or at the rate of 20l. per hour. In this calculation we expect we have not a fair representation of all the conditions. To obtain a light for ten minutes, a battery as large must be used as if it were required to be maintained in activity for hours—and probably the battery was charged anew every evening. There can be no doubt but the cost of light or of any other force from electricity, with our present means of producing it, must be greatly in excess of any of our ordinary means of producing illumination. For a consideration of this subject, see ELECTRO-MOTIVE ENGINE. Mr. Grove proposed a light which should be obtained from incandescent platinum, but the objection to this was, that after a short period, the platinum broke up into small particles, the electric current entirely disintegrating the metal. Mr. Way has lately exhibited a very continuous electric light, produced from a constant flow of mercury rendered incandescent by the passage of the electric current.

ELECTRIC WEAVING. M. Bonelli devised a very beautiful arrangement, by which all the work of the Jacquard loom is executed by an electro-magnetic arrangement. The details of the apparatus would occupy much space in the most concise description, and as the invention has not passed into use, although M. Froment has modified and improved the machine, we must refer those interested in the subject to the full description given in *De la Rée's Treatise on Electricity* by Walker.

ELECTRO-GILDING BATH. See CRYSTAL.

ELECTRO-METALLURGY. The art of working in metals was carried on exclusively by the aid of fire until the year 1839. At that epoch a new light dawned upon the subject; considerable interest was excited in the scientific world, and much astonishment among the general public by the announcement that electricity, under proper management, and by most easy processes, could supersede the furnace in not a few operations upon metals; and that many operations with metals, which could scarcely be entertained under the old condition of things, might be placed in the hands of a child, when electricity is employed as the agent.

Public attention was first directed to the important discovery by a notice that appeared in the *Athenæum* of May 4, 1839, that Professor Jacobi of St. Petersburg had "found a method of converting any line, however fine, engraved on copper, into a relief, by galvanic process." Jacobi's own account of the matter was that, while at Dorpat, in February, 1837, prosecuting his galvanic investigations, a striking phenomenon presented itself, which furnished him with perfectly novel views. Official duties prevented his completing the investigation, thus opened out to him, during the same year; and it was not until October 5, 1838, that he communicated his discovery, accompanied with specimens, to the Academy of Sciences at St. Petersburg; an abstract of which paper was published in the *German News* of the same place on October 30 of the same year. And in a letter of Mr. Lettoun, dated February 5, 1839, the nature of the discovery is thus given in the following March number of the *Annals of Electricity*. Speaking of a recent discovery of Professor Jacobi, he says, "He observed that the copper deposited by galvanic action on his plates of copper, could by certain precautions be removed from those plates in perfect sheets, which presented in relief most accurately every accidental indentation on the original plate. Following up this remark, he employed an engraved copper-plate for his battery, caused the deposit to be formed on it, and removed it by some means or other; he found that the engraving was printed thereon in relief (like a woodcut) and sharp enough to print from." This paragraph does not appear to have caught the eye of the public so readily as the briefer note that appeared a couple of months later in the *Athenæum*.

On May 8, or four days after the appearance of the notice in the *Athenæum*, Mr. Thomas Spencer gave notice to the Polytechnic Society of Liverpool that he had a communication to make to the society relative to the application of electricity to the arts. He subsequently desired to communicate the result of his discoveries to the British Association whose meeting was at hand; but, for some cause, which does not appear, the communication was not made; and it eventually was made public, as at first proposed, through the Polytechnic Society of Liverpool, on September 12, 1839. In the meantime, namely on May 22, Mr. C. J. Jordan, referring to the notice in the *Athenæum*, wrote to the *Mechanics' Magazine* that, at the commencement of the summer of 1838, he had made "some experiments with the view of obtaining impressions from engraved copper plates by the aid of galvanism." His letter describing this process appears in the number for June 8. It occurred to him, from what he had gathered from previous experience, that an impression might be obtained from an engraved surface; and so it was, "for on detaching the precipitated metal, the most delicate and superficial markings, from the fine particles of powder used in polishing to the deeper touches of a needle or graver, exhibited their correspondent impressions in relief with great fidelity."

Mr. Spencer in his communication, besides noticing the fidelity with which the traces on an original plate were copied, recorded the case of a copper plate that had become covered with precipitated copper, excepting in two or three places, where by accident some drops of varnish had fallen; whence it occurred to him, and experiment confirmed his conjecture, that a plate of copper might be varnished, and a design made through the varnish with a point, and copper might be deposited upon the metal at the exposed part, and thus a raised design be procured.

In the *Philosophical Magazine* for December, 1836, Mr. De la Rue, after describing a form of voltaic battery, refers in the well-known condition on which the properties of the battery in question mainly depend, that "the copper-plate is also covered with a coating of metallic copper, which is continually being deposited; and he goes on to describe that "so perfect is the sheet of copper thus formed, that being stripped out, it has the counterpart of every scratch of the plate on which it is deposited." Daniell himself, whose battery is here in question, noticed as he could not fail to do in common with all who had employed his battery to any extent, the same peculiarities; but it does not appear that either he or De la Rue, or any one else, to whom the phenomenon presented itself before Jacobi, Jordan, or Spencer, caught the idea of its applicability in the arts. It would also appear that the impression came with the greater vividness to the two latter; for, while but little time seems to have been lost to them in realising their idea, twenty long months elapsed between the time when the "perfectly novel views" first presented themselves to Professor Jacobi, and the time when his "well developed galvanic production" was communicated to the Imperial Academy of Science. But, on the other hand, neither Mr. Jordan nor Mr. Spencer appear, as far as we are aware, to have been so sensible of the importance of the results to which they had arrived as to have taken any steps to secure them as an invention or to publish them, until their attention was aroused by the previous publication of the successes of Jacobi.

Jacobi's "Galvano-plastik," Smees and also Shaw's "Electro-metallurgy," Walker's

"Electrotype Manipulation," four well-known works on the subject before us, present the different names under which the art is known; and from which it is gathered that metals may become, as it were, plastic under the agency of galvanic electricity, and may be worked and moulded into form. Voltaic pairs are described in general terms in the article on *ELECTRO-TYPEMANSHIP*. The particular voltaic pair which led to the discoveries now before us, here requires special notice; because, on the one hand, while in use for other purposes, it was the instrument which first directed attention forcibly to the behaviour of metals under certain conditions of electric current; and, on the other hand, it has been itself extensively used in electrotype operations. Professor Daniell first described his mode of arranging a voltaic pair in the *Philosophical Transactions* for 1836. Fig. 693 shows one cell complete of Daniell's combination, which from its behaviour is called a constant battery. A is a copper vessel;

693

n a rod of zinc, contained in a tube C of porous earthenware. The liquid within the tube C is salt and water, in which case the zinc is in its natural state; or, sulphuric acid and water, in which case the zinc is amalgamated; the latter arrangement being the more active of the two. The liquid in the outer vessel A, consists of crystals of sulphate of copper, dissolved in water. At C is a perforated shelf of copper below the surface of the liquid, upon which are placed spare crystals of sulphate of copper, which dissolve as required, and serve to keep up the strength of the solution in proportion as the copper already there is extracted by the voltaic action hereafter to be described. a and b are screws, to which wires may be attached, in order to connect up the cell and convey the current from it into any desired apparatus. Certain chemical changes take place when this instrument is in action; oxygen from the water within the porous tube combines with zinc, making oxide of zinc, which enters into combination with sulphuric acid, producing as a final result sulphate of zinc; hydrogen is liberated from water in the outer cell, and itself liberates oxygen from oxide of copper, and combines with it producing water, and leaving copper free. As far as the metals are concerned, zinc is consumed from the rod B, at the one end, and copper is liberated upon the plate A, at the other end. These actions are slow and continuous; and the copper, as it is liberated atom by atom, appears upon the inner surface of the cell; and after a sufficient quantity has been accumulated, may be peeled off or removed; when it will be found to present the marks and features of the surface from which it has been taken, and which, as we have already said, arrested the

696

attention of many into whose hands this instrument fell. A slight modification of the above arrangement gives us a regular electrotype apparatus. The cell C in this arrangement (fig. 696), is of glass or porcelain, or gutta serena, filled as before with a saturated solution of sulphate of copper, to which a little free acid is generally added; it is provided with a shelf or other means of suspending crystals of sulphate of copper. A zinc rod Z is placed in a porous tube P, as already described; and M, the other metal of the voltaic pair, is suspended in the copper solution and connected with the zinc Z by the wire W. The electric current now passes; zinc is consumed, as in fig. 693, but copper is now deposited on the metal M front and back, and on as much of the wire W as may be in the liquid; or, if Mr. Spencer's precaution is taken of varnishing the wire and the back of the metal M, all the copper that is liberated will be accumulated on the face of M. If salt and water or very weak acid water is contained in the porous tube P, and the zinc Z does not considerably exceed in size the metal M, the conditions will be complied with for depositing copper in a compact regular form.

It is obvious that, with this arrangement, M may be a mould or other form in metal, and that a copy of it may be obtained in copper. Fusible metal, consisting of 4 parts of bismuth, 4 of tin, 5 of lead, and 1 of antimony; or 8 parts bismuth, 3 tin, and 3 lead, is much used for taking moulds of medals. The ingredients are well melted together and mixed; a quantity sufficient for the object in view is poured upon a slab or board and stirred together till about to set; the film of dross is then quickly cleared from the surface with a card, and the cold medal is either projected upon the bright metal, or being previously fitted in a block of wood is applied with a sudden blow. Moulds of wax or stearine variously combined, or more recently and better in many cases, moulds of gutta serena, are applicable to many purposes. But, as none of these latter materials conduct electricity, it is ne-

necessary to provide them with a conductive surface. Plumbago or black lead is almost universally employed for this purpose; it is rubbed over the surface of the mould with a piece of wool on a soft brush, care being taken to continue it as far as to the conducting wire, by which the mould is connected with the zinc. With moulds of solid metal, the deposit of copper commences throughout the entire surface at once; but, with moulds having only a film of plumbago for a conductor, the action commences at the wire and extends itself gradually until it has been developed on all parts of the surface.

The nature of the electro-chemical decompositions that are due to the passage of voltaic currents through liquids, especially through liquids in which metal is in certain forms contained, can be best understood by studying the arrangement that is most commonly used in the arts, wherein the voltaic apparatus, from which the electric current is obtained, is distinct and separate from the vessel in which the electro-metallurgical operations are being brought about. Such an arrangement is shown in *fig. 697*, where *A* is a Daniell's cell, as in *fig. 695*; and *B* a trough filled with

697

an acid solution of sulphate of copper; *m* is a metal rod, on which the moulds are hung; and *c* a metal rod, upon which plates of copper are hung facing the moulds; the copper plates are connected by the wire *z* with the copper of the battery cell, and the moulds by the wire *x* with the zinc rod. The voltaic current is generated in the cell *A*, and its direction is from the zinc rod, through the sulphate solution of the cell; thence by the wire *z* to the plates of copper *c*; through the sulphate solution to the moulds *m*; and thence by the wire *x* to the zinc rod. In this arrangement, no shelf is necessary in the trough *B* for crystals of sulphate of copper to keep up the strength of the solution; for the nature of the electro-chemical decomposition is such, that in proportion as copper is abstracted and deposited on the moulds, other copper is dissolved into the solution from the plates *c*. Water is the primary subject of decomposition. It is a compound body, consisting of the gases oxygen

698

and hydrogen, and may be represented by H_2O , where the arrows show the direction in which the current, by the wire *p*, enters the trough *B* of *fig. 697* by the plate of copper *c*, and passes through the water in the direction shown, and leaves it after traversing the mould by the wire *n*. Two atoms of water $O H$ and $O' H'$, as bracketed 1 and 2, are shown to exist before the electric current passes; and two atoms, one of water $H O'$ (bracketed 1), and one of oxide of copper $O C$, has come into the solution; and, on the other hand, the one hand an atom of copper *c* has come into the solution; and, on the other hand, the atom of hydrogen H , belonging to the second atom of water is set free and rises in the form of gas. The explanation is to show that oxygen is liberated where the current enters, and combines there in its nascent state with copper; it would not have combined, for instance, with gold or platinum. We might easily extend this symbolical figure, and show how that, when free sulphuric acid is in the solution, the oxide of copper on its formation combines with the acid to produce the sulphate of copper required; and how, when free sulphate of copper is present, the hydrogen, instead of being freed in the form of gas, combines with oxygen of the oxide of copper, and liberates the metal, which in its nascent state is deposited on the mould, and produces the electrolytic copy of the same. One battery cell is sufficient for working in this way in copper; it is increased in size in proportion to the size of the object operated upon. And, although for small subjects, such as medals, a vertical arrangement will act very well; for large objects, it has been often found of great

advantage to adopt a horizontal arrangement, placing the mould beneath the copper plate. The varying density of a still solution in the vertical arrangement is not without its effect upon the nature of the deposit, both on its character and its relative thickness. This has been in some instances obviated, and the advantage of the vertical method retained by keeping the solution in motion, either by stirring or by a continuous flow of liquid.

We have described principally Daniell's battery as the generating cell in Electro-metallurgical operations; but Mr. Smee's more simple arrangement of platinized silver and zinc, excited with diluted sulphuric acid, has been found in practice more economical and convenient.

Fig. 699 is a Smee's cell: a vessel of wood, glass, or earthenware, contains diluted sulphuric acid, one in eight or ten, a platinized silver plate *a*, sustained by a piece of wood *x*, with a plate of zinc *z* on each side, so as to turn to useful account both sides of the silver plate. The zinc plates are connected by the binding screw *b*. Platinization consists in applying platinum in fine powder to the metallic surface. When hydrogen is liberated by ordinary electric action upon a surface so prepared, it has no tendency to adhere or cling to it; but it at once rises, and in fact gets out of the way, so that it never, by its presence or lingering, interferes with the prompt and ready continuance of the electric action; and in this way, the amount of supply is well kept up.

Platinization is itself another illustration of working in metal by electricity. A few crystals of chloride of platinum are dissolved in diluted sulphuric acid. A voltaic current is made to enter this solution by a plate of platinum and to come out by a silver plate. Two or three Daniell's or Smee's cells are necessary for the operation. The chloride of platinum is decomposed, and the metal is deposited upon the silver plate; not, however, in the reguline

compound form, as in the case of copper, but in a state of black powder in no way coherent. This affords also an illustration of the different behaviour of metals under analogous circumstances. Copper is of all metals the most manageable; platinum is among the more unmanageable.

Mr. C. V. Walker has, with great advantage, substituted graphite for silver. The material is obtained from gas retorts, and is cut into plates a quarter of an inch thick, or thicker, when plates of a larger size are cut. He platinizes these plates in the usual way as above described, and deposits copper on their upper parts, also by electrolytic process, and solders a copper slip to the electrolytic copper, in order to make the necessary connection.

With the exception of silver and gold, copper is the metal which has been most extensively worked by these processes.

SEALS are copied by obtaining impressions in sealing-wax, pressing a warm wire into the edge for a connection; rubbing blacklead over the wax to make the surface conductive; fastening a slip of zinc to the other end of the wire; wrapping the zinc in brown paper, and putting the whole into a tumbler containing sulphate of copper, a little salt-water having been poured into the brown paper cell.

PLASTER or PARIS MEDALLIONS may be saturated with wax or stearine, and then treated, if small, like seals; if large, in a distinct trough, as in fig. 697. In this case the copy is in intaglio, and may be used as a mould for obtaining the facsimile of the cast. More commonly, the cast is saturated with warm water, and a mould of it taken in wax, stearine, or gutta percha. This is treated with blacklead, and in other respects the same as seals.

WOODCUTS are treated with blacklead, and a copper reverse is deposited upon them. This is used as a mould to obtain electrolytic duplicates, or as a die for striking off duplicates.

STEREOTYPE PLATES are obtained in copper by taking a plaster copy of the type, treating it plaster fashion, depositing a thin plate of copper upon it, and giving strength by backing up with melted lead.

OLD BRASSES may be copied by the intervention of plaster.

ENGRAVED CARDS OR PAPER may be copied by first saturating with wax and then using blacklead.

PAPER may be copied by the intervention of moulds, or may be covered with copper. LEAVES, TWIGS, and BRANCHES may have copper deposited upon them. The same for STATUETTES, BUSTS, and STATUES.

LEAVES and FLOWERS are furnished with a conducting surface by dipping them into a solution of phosphorus in bisulphuret of carbon, and then into a solution of nitrate of silver. Silver is thus released in a metallic state upon their surface.

PLASTER BUSTS, &c., have been copied in copper, by first depositing copper on the plaster prepared for this operation; when thick enough, the original bust is dissolved, the copper shell is filled with sulphate of copper, as in *fig. 697*, and copper is deposited on its inner surface till of sufficient thickness; the outer shell is then removed.

TURNS and VESSELS of capacity do not appear to have been profitably multiplied by electrolysis.

PLATES have been prepared for the **ENGRAVER** to work on by depositing copper on polished copper-plates, and removing the deposits when thick enough.

For the multiplication of **ENGRAVED COPPER PLATES**, the electrotype process has been very extensively adopted. A reverse of the plate is first obtained by the deposition of copper; this serves as a mould, from which many copies of the original plate are obtained by depositing copper upon it, and then separating the two. The mode practised by the Duke of Leuchtenberg is to print from an engraved plate on very thin paper with a mixture of resin of Damara, red oxide of iron, and essence of turpentine. While the impression is wet, the paper face downwards is pressed upon a polished plate of copper. When dry the paper is washed away, and the impression remains. An electrotype copy from this is obtained in intaglio, and is fit for the use of the printer.

GALVANOGRAPHY is a picture drawn originally in varnish on the smooth plate, and then treated in a similar way to the above.

The **PLATES** on rollers used by **CALICO PRINTERS** have been multiplied like engraved plates.

GLYPHOGRAPHY is a name given by Mr. Palmer to his process. He blackens a fair copper-plate with sulphuret of potassium, covering it uniformly with a coating of wax and other things, then draws the design through the wax with fine tools. From the plate thus prepared, an electrotype is taken in the usual way, and is backed up and mounted as an electro-glyphic cast to print from as from a wood block. For a *stereoglyphic* cast to work from as a stereotype plate, a plaster copy is taken of the original drawing, the high lights are cut out, and then an electrotype copy is made.

ELECTRO-TINT is done by drawing with wax or varnish any design on a fair copper-plate, and making an electrotype copy for the printer's use.

FERN-LEAVES, &c., are copied by being laid on a sheet of soft gutta percha, pressed into the surface by a smooth plate to which pressure is applied, and then removed in order to subject the gutta percha mould to the electrotype process. This is **NATURAL PAINTING**, which see.

MM. Auer and Worring have copied **LACE, EMBROIDERY**, flowers, leaves of trees, entire plants, fossils, insects, &c., in their natural relief, by laying the objects upon a plate of copper, after having soaked them in spirits of wine and turpentine so as to fix them. A plate of clean lead is laid over, and, on being pressed, an intaglio copy is produced on it of the object. From this an electrotype is obtained.

UNDERCUT MEDALLIONS, &c., are copied in elastic moulds made of treacle and glue in the proportions of 1 to 4. Masks and busts may also be obtained in such moulds.

ELECTRO-CLOTH was made by saturating the fibre of canvass or felt, making it conductive in the usual way; it was proposed in place of tarpaulins as a water-tight cover.

RETURNES and CRUTCHES, &c., of glass or porcelain, have been successfully coated with electrotype copper by first varnishing or otherwise preparing the surface to retain the black lead, and then treating them as usual.

SOLDERING COPPER surfaces has been accomplished by galvanic agency. The ends to be united are placed together in the solution of sulphate of copper, and connected with the battery as for ordinary deposition. Parts not included in the process are protected off by varnish; copper is then deposited, so as to unite the separate pieces into one.

IRON may be coated with copper. But here a new feature comes into view. Sulphuric acid leaves the copper of the sulphate combines with iron and deposits copper on its surface without the aid of the voltaic apparatus. The iron surface is immediately covered with copper, no firm perfect deposit occurs. In order to obtain a solid deposit of copper on iron, it is necessary to use a solution that has no ordinary chemical reaction upon iron. Cyanide of copper is used, which may be obtained by dissolving sulphate of copper in cyanide of potassium. This solution requires to be raised to and retained at a temperature not greatly below 200°, in order to give good results.

ELECTRO-ZINCING is applied to surfaces of iron, in order to protect them from corrosion. A solution is made of sulphate of zinc, which is placed in a trough,

fig. 697. Two or three battery cells are required. The iron to be zincd is connected with the zinc end of the battery, and a plate of zinc with the copper end.

VOLT-*AI*C *MASS* does not appear to have been obtained in a solid distinct form, but has been successfully produced as a coating upon a copper surface. Separate solutions are made of sulphate of copper and of sulphate of zinc in cyanide of potassium. The two solutions are then mixed, and placed in a decomposing trough.

Two or three cells of a battery are used, and a brass plate connected with the copper end. An electrotype copper medal or other prepared surface is connected with the zinc. Brilliant and perfect brass soon appears, and will deposit slowly for some hours; but after a while, the character of the solution changes, and copper appears in place of brass.

This hasty glance at the leading applications of this art will give an idea of its utility. It also comes into play in cases where least suspected. Pins were tinned by electrotype long before the art was known. Brass pins are thrown into solution of tin in cream of tartar, and are unchanged; but when a lump of tin is thrown among them, a voltaic pair is formed, and tin is deposited on all the brags. Any stray pins detached from the mass, escape the influence. Space would fail us were we to go through the list of crystalline and of simple bodies formed by these processes; as for instance, octahedral crystals of protoxide of copper; tetrahedral crystals of proto-chloride of copper; octahedral crystals of sulphide of silver; crystals of subnitrate of copper; bitumic carbonate of copper, and others too numerous to name, have all been formed by slow voltaic actions. The alkaline metals, potassium, sodium, &c., were first obtained by Davy in the galvanic way; magnesium, barium, aluminium, calcium, &c., are obtained by M. Bunsen by operating upon the chlorides of these metals either in solution or in a state of fusion.

ELECTRO-ETCHING is produced at the place where the current enters the decomposing trough, as at the copper-plates of *fig. 697.* A plate of copper is prepared as if for the graver; its face is then covered with an etching ground of asphalt, wax, black pitch, and burgundy pitch; and its back with varnish. The design is then traced through the etching ground with a fine point; the plate is then placed in the trough, containing either sulphate of copper or simply diluted sulphuric acid, and connected with the copper of the battery. After a few minutes it is removed, and the fine lines are stopped out with varnish; it is then replaced, and again, after a few minutes is removed, and the darker shades are stopped out; the parts still exposed are again subjected to the action, and the etching is complete. When the ground is removed, the design will be found etched upon the copper-plate ready for the printer.

DAGUERRETYPE ETCHING is a delicate operation, and requires much care. The solution employed by Professor Grove was hydrochloric acid and water in equal parts, and a battery of two or three cells.

Platinized silver is used in place of the daguerreotype, instead of copper. The result comes out in about half a minute. An oxy-chloride of silver is formed, and the mercury of the plate remains untouched.

A *PHOTO-GALVANO-GRAPHIC* Company has been formed in London for carrying out the process of Paul Preteck. He makes solutions of bichromate of potash in glass water, or in solution of gelatine, instead of in pure water. He then treats the glass or plate with these, and in the usual way takes a picture. He washes the gelatine picture with water, or solution of borax or carbonate of soda, which leaves the picture in relief; when developed, he washes with spirits of wine, and obtains a sunk design. The surfaces thus prepared, or moulds made from them in one or other of the modes already described, are placed in a galvano-plastic apparatus for obtaining an engraved plate from which to print. See *PHOTO-GALVANOGRAPHY*.

The Duke of Leuchtenberg prepares a plate for etching by leaving the design on the ground, and removing the ground for the blank parts. When his electrotype operation is complete, the design is in relief instead of being in intaglio as in ordinary etching.

METALLO-CHROMES consist of thin films of oxide of lead, deposited sometimes on polished plates of platinum, but more commonly on polished steel plates. The colours are most brilliant and varied. Nobili is the author of the process.

A saturated solution of acetate of lead is prepared and placed in a horizontal trough. Three or four battery cells are required. A steel plate is laid in the acetate of lead with its polished surface upward, and is connected with the copper of the battery. If a wire is connected with the zinc end of the battery, and held over the spot immediately beneath the wire, and expand and spread, like the circles when a stone is thrown into a pond. Silver-blond is the first colour; then fawn-colour, followed by the various shades of violet, and indigo and blues; lake, bluish lake,

green and orange, greenish violet, and passing through reddish yellow to rose lake, which is the last colour in the series.

According to the shape of the metal by which the current enters — be it a point, a slip, a cross, a concave, or a convex disc — so is the form of the coloured figure varied. And if, in addition to this, a pattern in card or gutta serena is cut out and interposed between the two surfaces, the action is intercepted by the portions not removed, and the design is produced on the steel plate, in colours, that may be greatly varied, according to the duration of the experiment. The different colours are due to the different thicknesses of the thin films of peroxide of lead.

M. Berquard prepared the deposit of peroxide of lead, and also the red peroxide of iron, for protecting metals from the action of the atmosphere. For the latter, proto-sulphate of iron is dissolved in ammonia solution, and operated upon by two or three batteries.

The most important application of electro-metallurgy in the arts has been for PLATING and GILDING, which is most extensively carried on both at home and abroad. Results that were unobtainable, and others attainable only at great cost, are readily produced by this mode of manipulating. The liquids most in use are the cyanide solutions, first introduced by Messrs. Elkington. They are prepared in various ways. Cyanide of potassium is added carefully to dilute solution of nitrate of silver; and the white deposit of cyanide of silver is washed, and then dissolved in either cyanide of potassium; or lime water is added to the nitrate solution, and the brown deposit of oxide of silver is washed and, while moist, is dissolved in cyanide of potassium; or common salt is added to the nitrate solution, and the white deposit of chloride of silver is washed and dissolved in cyanide of potassium. Or a solution of cyanide of potassium is placed in the trough *b*, fig. 697; and the current from three or four cells is passed into it from a silver plate at *c*, which combines with acid is dissolved into the liquid, converting it into a cyanide of silver solution. To prevent silver being abstracted by deposition at *a*, as the current leaves the trough, the metal at *a* is placed within a porous cell of cyanide solution, so as to limit the action.

Gold solution is obtained by dissolving the anhydrous peroxide of gold in cyanide of potassium, or by treating chloride of gold with cyanide of potassium, or by using a gold plate and a voltaic current with a solution of cyanide of potassium in the same way as described for silver; and allowing the action to continue until the solution is sufficiently strong of gold. With these solutions electro-plating and gilding are readily accomplished. There are other solutions more or less valuable, which will be found in the books that treat upon the subject.

Fig. 700 shows a simple cell arrangement for plating. The sink is outside, and is bent to embrace both sides of the porous cell. The article to be plated is within this

cell; because, being the vessel of smaller capacity, less of the more valuable silver solution is required, and there is less of loss or waste. The same holds good in a greater degree of gold. In a few minutes, the article is covered with silver. If a few drops of sulphuret of carbon are added to the silver solution, the silver is deposited bright. Gold does not come down quite so rapidly as silver.

Except for mere experiment, these operations are better accomplished and with less waste by using distinct batteries, as *a*, fig. 701, the solution of gold or silver being in a distinct trough *b*, plates of silver or gold, as the cases may be, being suspended in front of the article to be coated. One or two cells, according to the results required, are used for plating; and three or four for gilding. But gilding is never so

well accomplished as it is with hot solutions. The modes of keeping solutions hot vary with circumstances, and with the extent of the operations. Fig. 702 is

arrangement for operations on a small scale. The vessel *a* *b*, containing the gold solution, rests over a small stove or spirit-lamp. The objects to be gilt are suspended by wires to the conducting rod *d*, in connection with the zinc end of the battery; and the gold wire or plate *e* is connected with the other end. A temperature of from 100° to 200° is desirable; the higher temperatures require fewer battery cells; with the highest, one will suffice. The solution of course evaporates under the influence of heat; and distilled water must be added to supply the loss, before each fresh operation.

Plating and gilding is successfully and, in point of economy, advantageously carried on at Birmingham, in more than one manufactory, by means of magneto-electricity. In the article on ELECTRIC-TELEGRAPHY will be found a description of this form of electric force; and the means by which it is produced. An electro-magnet is set in motion in front of the poles of a permanent magnet, in such a manner that the soft iron core of the electro-magnet becomes alternately a magnet and not a magnet; in the act of becoming a magnet, it raises up a current in one direction in the wire with which it is wound; in the act of ceasing to be a magnet, it raises up a current in the reverse direction. The ends of the wire are led away and insulated. The instru-

703

ment is fitted with a commutator, so adjusted that it collects the currents from the ends of the wire, and guides them in a uniform direction into the vessel that contains the solution and articles to be gilded or plated. In practice, a single machine consists

of many electro-magnets grouped together, and many powerful magnets for exciting them; by which means a continuous flow of a large amount of electricity is obtained. Fig. 703 is an illustration of such an arrangement as adapted by Mr. Woolrich: *a a a a* are four clusters of permanent steel magnets, seen from above; *b b b b b* is the frame-work of the machine; *c c c c* are four bars of soft iron, wound with large size insulated copper wire; *d* is a circular disc, on which they are mounted, and which rotates on a vertical axis, of which *f* shows the upper end; *e* is the commutator, from which two wires are led off to the solution to be operated upon. The permanent magnets are U shaped; one pole only of each bundle is visible; the other is beneath the disc *d*, and its freight of electro magnets *c c c c*, &c. The axis is set in rotation by a shaft passing over the drum of a shaft of the steam-engine, that does the ordinary work in a factory; and the disc carries the electro-magnets between the poles of the permanent magnets, and exposes them to the most favourable action of these poles. The number of coils and magnets vary in proportion to the work required. By this arrangement, not only does each coil pass under the influence of many magnets, but each magnet acts successively on many coils; and a proportionate supply of electricity is the result.—C. V. W.

ELECTRO-MOTIVE ENGINES. The following remarks on this subject are an abstract of a communication read by the editor to the *Institution of Civil Engineers*, for which they awarded him their Telford Medal.

Numerous electro-magnetic machines have been made, but a few only of these require to be described. In 1832, Salvatore Dal Negro published an account of the attempts made by him in this direction. As Dal Negro's engine was of a very simple and effective kind, the Professor's description of it may be quoted:—"As I had been successful in producing temporary magnets of very great power, with very small electro-motors, I endeavoured to apply this power to moving machinery. I will now briefly state by what means I endeavoured to set a lever in motion. I first used a magnetic steel bar, placed vertically between one end of a temporary magnet. The bar vibrated from the attractions and repulsions which took place between its north pole and the north and south poles of the electro-magnet. In the same way a motion may be effected in a horizontal plane. I also set in motion a similar bar, by allowing a piece of iron, set free from the magnet at the moment when its power became = 0 to fall on one of its ends, after this it was immediately re-attracted. This can be effected in two ways: the one may be employed when a quick motion is to be produced and the second when a greater force is wanted; in the first case the weight falls only just out of the power of the magnet's attraction, and the instant the weight has fallen upon the bar, or lever, it is re-attracted by the magnet that the action may be repeated: it is always small in comparison with that which the magnet cannot support whilst in contact. In the second case the whole weight which the magnet can carry is employed, and use is made of the force which draws it to the magnet." Upon this was founded several other attempts particularly one by Dr. Schott, who was so satisfied with the result, that he wrote in 1833:—"If we consider that electro-magnets have already been made, which were capable of carrying 20 cwts, and that there is no reason to doubt that they may be made infinitely more powerful, I think I may boldly assert, that electro-magnetism may certainly be employed for the purpose of moving machines." Professor Biondi of Turin, also employed "a lever put in motion (in the manner of a metronome) by the alternating of two fixed electro-magnetic cylinders, exerted on a third movable cylinder, connected with the lower arm of the lever, the upper part of which maintains a metallic wheel, serving in the ordinary way, as a regulator in a continuous gyratory motion." It will be evident to any one who has observed the motion of many of the electric clocks, that this is in several respects similar to the pendulous motions adopted.

In 1835, Professor Jacobi, of St. Petersburg, published an account of his experiments, which were carried out on a large scale, regardless of cost, at the expense of the Emperor Nicholas. His first idea was to employ the attractive and repellant powers of magnetic bars, so that he might obtain an advancing and receding motion, which could be easily changed into a continuous circular motion. A great many machines have been made upon this principle; but Jacobi, alone, as far as can be learned, has pointed out the true cause of their failure. "We know," he says, "the ill effects of shocks in the movements of machines, but there is here, another inconvenience which is not simply mechanical. The soft iron, by these repeated shocks and vibrations, gradually acquires at the surface of contact the nature of steel; there will be a considerable permanent magnetism, and the transient magnetic force which alone produces the movement, will be weakened in proportion. A number of experiments, which I have made upon the magnetic force of a bar of soft iron, put into a horseshoe form, has shown me the great disadvantage of often repeated shocks, proceeding from the sudden contact of the armature."

Jacobi, finally settling all oscillating motions, produced a machine giving continuous circular motion, by fixing eight electro-magnetic bars on a disc, movable round its axis—and eight fixed bars similarly arranged upon a fixed platform. The arrangement of the bars admitted of much variety, provided it was exactly symmetrical, and that it allowed the poles to approach each other as nearly as possible. Arrangements were made, with much ingenuity, by which the poles of the magnets were inverted directly, and so that that inversion should take place precisely at that point where the bars were opposite each other. One hundred and forty-four inversions in the second were readily effected, and Jacobi declared it would be easy with his apparatus "to change, or to completely interrupt, the electric current, one thousand, or more, times in a second."

A machine constructed upon this principle was, at the desire and at the cost of an Imperial Commission, put on board a ten-oared shallop, equipped with paddle-wheels, to which the electro-magnetic engine communicated motion. The boat was 20 feet long, and 7½ feet in width, and drew 2½ feet of water. In general, there were on or twelve persons on board, and the voyage on the Neva was continued during several entire days. By these experiments Jacobi was led to the conclusion, that a battery of 20 square feet of platinum would produce power equivalent to one horse; and the vessel went at the rate of four miles an hour. In 1839, Jacobi tried another experiment, with a battery of 64 platinum plates, each having 36 square inches of surface; when the boat, with a party of 14 persons on board, went against the stream at the rate of 3 miles an hour.

In 1837, Mr. Thomas Davenport, of the United States, constructed a rotary engine, in which permanent and electro-magnets were employed. Mr. Taylor, in 1839, patented an electro-magnetic engine, both in America and in this country, the principal novelty in which was, that instead of changing the poles of the magnets, the electric action was, at fixed rapid intervals, entirely suspended. In 1837, Mr. Davidson, of Edinburgh, constructed an engine, in which he produced motion by simply suspending the magnetism, without a change of the poles. Mr. Robert Davidson placed an electro-magnetic locomotive on the Edinburgh and Glasgow Railway; the carriage was 16 feet long, and 6 feet broad, and weighed at 3 tons. All the arrangements appear to have been very complete, but when put in motion on the rails, it was not possible to obtain a greater speed than four miles an hour.

Professor Page's electro-magnetic engine was for some time looked upon as a triumph. The fundamental principle of it is thus described: "It is well known that when a helix of suitable power is connected with the poles of a battery in action, an iron bar, within it, will remain held up by the induced magnetism, although the helix be placed in a vertical position; and if the bar is partly drawn out of the helix by the hand, it goes back with a spring, when the hand lets go its hold. This power, —the action of the helix upon the metallic bar within it,—is the power used in Page's engine." Professor Page exhibited one of his engines, of between 4 and 5 horse-power, at the Smithsonian Institution; the battery to operate with being contained within a space of 3 cubic feet. It was a reciprocating engine of 2 feet stroke, and the whole, including the battery, weighed about one ton. Professor Page stated, that the consumption of 3 lbs. of zinc per day would produce one horse-power. This statement requires further investigation.

Many similar attempts have been made, to construct effective machines to be moved by the power of the voltaic battery. Among others, Mr. Henley constructed an electro-magnetic engine of considerable power, for Mr. Talbot, and another for Professor Wheatstone. In these there were many ingenious mechanical arrangements, invented to overcome some of the difficulties hitherto encountered; but the physical conditions were similar to those already described. Mr. Talbot's engine was 3 feet 6 inches long, and 2 feet 6 inches wide; when excited by a Grove's battery, consisting of four cells with double plates of zinc, 9 inches by 6½ inches, platinum plates 9 inches by 6½ inches, excited by diluted sulphuric acid in the proportions of 1 to 4, and concentrated nitric acid, it drove a lathe, with which was turned a gun-metal pulley 5 inches in diameter; but in three quarters of an hour the battery was quite exhausted.

Mr. Hirsch, a few years since, exhibited in London a large machine, constructed somewhat on the principle of Page's; this, however, failed to produce any great mechanical effect, and it appears to have been abandoned. Dr. Lardner stated, in 1851, that M. Gustave Frimont, of Paris, was using, with much advantage, an electro-magnetic engine in his workshops for turning lathes, planing machines, &c. Its use, however, appears to have been abandoned, on account of the great cost of the battery power.

Haukel and Fessel, on the Continent, the Rev. James William McQualey, Dr. Kemp, and others, in Great Britain, have, at different times, excited much attention by the ingenious machines which they have constructed.

Notwithstanding these numerous trials, and, connected with them, an almost infinite amount of experiment, it does not appear, that any satisfactory explanation has ever been given of the causes which have led to the abandonment of the idea of employing electricity as a motive power. It was mainly with the view of directing attention to these causes, that the essay read was written.

Electro-magnetism undoubtedly affords an almost unlimited power. An electro-magnet may be constructed which shall have a lifting power equal to many tons. It is probable, that there are limits beyond which it would not be possible to increase the power of electro-magnets; those limits have not yet been reached; but supposing them to be attained, there is nothing to prevent the multiplying of the number of electro-magnets in the arrangements. It may be stated, in connection with this part of the subject, that from experiments made with Haeuser's magnetometer, it appears that the development of magnetism in iron observes some special peculiarities. These may be thus stated:—With the same electro-magnet there is, as the volta's pairs in the battery are increased, a gradual increase of magnetic force. With from one to seven elements there appears an average excess of 31 lbs.; after this point, with the increase of battery power, by the addition of pair after pair of zinc and platinum elements, the production of power bears a decreasing ratio to the power employed, and at last, the addition of five elements was not found to produce an increase of effect equivalent to the value of one element. In all experiments, therefore, on electro-magnetic machines, the experimenter has first to determine the utmost power which the soft iron is capable of assuming, in relation to,—1st. The number of coils of wire on the iron; and 2nd, the number of elements employed in the exciting source—the volta's battery. The length of the iron and its thickness are also points demanding special considerations from the construction of an electro-magnetic machine.

There remains now to examine the production of the power, Electro-Magnetism.

The electro-mechanician is dependent upon his battery, in the same way as a steam engineer is dependent upon his fire and his boiler, for the production of mechanical effect.

Voltaic batteries vary in their effects, and hence arise statements which differ widely from each other, as to the result obtained, by the destruction (or change of form) of a given quantity of metal in the battery.

Dr. Botta states, that 45 lbs. of zinc, consumed in a Grove's battery, are sufficient to work one-horse power electro-magnetic engine for twenty-four hours.

Mr. Joule says the same results would have been obtained, had a Daniell's battery been used, by the consumption of 75 lbs. of zinc.

It is impossible, on the present occasion, to enter into the theory of the voltaic battery, or to describe the varieties of arrangement which have been adopted for generating (developing) electrical force in the form of a current, with the greatest effect, at the smallest cost.

On this point the evidence of Jacobi may be quoted:—“With regard to the magnetic machine, it will be of great importance to weaken the effects of the counter current, without at the same time weakening the magnetism of the bars. It is the alternate combination of the pairs of plates in the voltaic pile, which permits us to increase the speed of rotation at will. We know the magnetic power of the current is not sensibly augmented by increasing the number of the pairs of plates, but the counter current is considerably weakened by its being forced to pass through a great many layers of liquid. In fact, on using twelve voltaic pairs, each, half a square foot, instead of four copper troughs, each with a surface two square feet, which I had hitherto used, the speed of rotation rose at least 250 or 300 revolutions in a minute.”

Mechanical force, whether obtained in the form of man-power, horse-power, steam-power, or electrical-power, is the result of a change of form in matter. In the animal, it is the result of muscular and nervous energy, which is maintained by the due supply of food to the stomach. In the steam-engine, it is the result of vapour pressure, which is kept up by the constant addition of fuel to the fires, under the boilers. In the magnetic machine, it is the result of currents circulating through wires, and these currents are directly dependent upon the chemical change of zinc or of some other metal in the battery. Then,

Animal power depends on food.

Steam power depends on coal.

Electrical power depends on zinc.

An equivalent of coal is consumed in the furnace—that is, it unites its carbon with oxygen to form carbonic acid, and its hydrogen with oxygen to form water, and during this change of state the quantity of heat developed has a constant relation to the chemical action going on.

Mr. Joule has proved by a series of most satisfactory experiments, that: "The quantity of heat capable of increasing the temperature of a pound of water by one degree of Fahrenheit's scale is equal to, and may be converted into, a mechanical force capable of raising 838 lbs. to the perpendicular height of one foot."

Mr. J. Scott Russell has shown that in the Cornish boilers, at Huel Towan and the United Mines, the combustion of one pound of Welsh coal evaporates of water, from its initial temperature, 1058° and 1048° respectively. "But," says Mr. Joule, "we have shown that one degree is equal to 138 lbs. raised to the height of one foot. Therefore the heat evolved by the combustion of one pound of coal is equivalent to the mechanical force capable of raising 2,384,206 lbs. to the height of one foot, or to about ten times the duty of the best Cornish engines."

Such are the conditions under which heat is employed as a motive power. An equivalent of zinc is acted on by the acid in the cells of the battery, and is oxidized thereby. In this process of oxidation a given quantity of electricity is set in motion; but the quantity available for use, falls very far below the whole amount developed by the oxidation of the zinc. The electricity, or electrical disturbance, is generated on the surface of the zinc; it passes through the acidulated fluid to the copper plate or platinum plate, and in thus passing from one medium to another, it has to overcome certain mechanical resistances, and thus a portion of the force is lost. This takes place in every cell of the voltaic arrangement, and consequently the proportion of zinc which is consumed, to produce any given mechanical result, is considerably greater than it should be theoretically.

Joule gives as the results of his experiments, the mechanical force of the current produced in a Daniell's battery as equal to 1,100,160 lbs. raised one foot high, per pound of zinc, and that produced in a Grove's battery as equal to 1,843,600 lbs. raised one foot high, per pound of zinc.

It need scarcely be stated, that this is infinitely above what can be practically obtained. A great number of experiments, made by the Author some years since, enabled him to determine, as the mean average result of the currents, produced by several forms of battery power, that one grain of zinc, consumed in the battery, would exert a force equal to lifting 20 lbs. one foot high. Mr. Joule and Dr. Seare by thus sum up a series of experimental results. "Upon the whole, we feel ourselves justified in fixing the maximum available duty of an electro-magnetic engine, worked by a Daniell's battery, at 80 lbs. raised a foot high, for each grain of zinc consumed." This is about one-half the theoretical maximum duty. In the Cornish engines, doing the best duty, one grain of coal raised 113 lbs. one foot high. The difference in the cost of zinc and coal need scarcely be remarked on. The present price of the metal is 33s. per ton, and coal can be obtained, including carriage to the engine, at less than 1s. per ton; and the carbon element does two-thirds more work than can possibly be obtained from the metallic one.

By improving the battery arrangements, operators may eventually succeed in getting a greater available electrical force. But it must not be forgotten, that the development of any physical force observes a constant law. Whether in burning coal in the furnace, or zinc or iron in the battery, the chemical equivalent represents the theoretical mechanical power. Therefore, the atomic weight of the carbon atom being 6, and that of the zinc atom being 32, it is not practicable, under the best possible arrangements, to obtain anything like the same mechanical power from zinc which can be obtained from coal. Zinc burns at an elevated temperature; in burning a pound of zinc there should be obtained, as heat, the same amount of mechanical power which is obtained as electricity in the battery. The heat being more easily applied as a prime mover, it would be far more economical to burn zinc under a boiler, and to use it for generating steam power, than to consume zinc in a voltaic battery for generating electro-magnetic power.

ELECTRO-PLATING AND GILDING IRON. Professor Wood, of Springfield, Massachusetts, in a paper, which he has communicated to the *Scientific American*, recommends the following as useful recipes for the electro-metallurgist. He says, "I believe it is the first time that a solution for plating direct on iron, steel, or Britannia metal has been published. In most of the experiments I have used Smee's battery; but for depositing brass I prefer a battery fitted up as Grove's, using artificial graphite—obtained from the inside of broken coal-gas retorts—to the place of platinum. With one large cell (the zinc cylinder being 8 x 3 inches, and excited with a mixture of one part sulphuric acid and twelve parts water, the graphite being excited with commercial nitric acid) I have plated six grains of polished iron needles per hour with brass. I have also coated type and stereotype plates with brass, and find it more durable than copper-facing."

To prepare Cyanide of Silver.—1. Dissolve 1 oz. of pure silver in 3 oz. of nitric acid and 2 oz. of hot water, after which add 1 quart of hot water. 2. Dissolve

5 oz. of the cyanide of potassium in 1 quart of water. To the first preparation add by degrees a small portion of the second preparation, until the whole of the silver is precipitated, which may be known by stirring the mixture and allowing it to settle. Then drop into the clear liquid a very small quantity of the second preparation from the end of a glass rod; if the clear liquid is rendered turbid, it is a proof that the whole of the silver is not separated; if, on the other hand, the liquid is not altered, it is a proof that the silver is separated. The clear liquid is now to be poured off, and the precipitate, which is the cyanide of silver, washed at least four times in hot water. The precipitate may now be dried and bottled for use. *To prepare Cyanide of Gold.*—Dissolve 1 oz. of fine gold in 1·4 oz. of nitric acid and 2 oz. of muriatic acid; after it is dissolved add 1 quart of hot water, and precipitate with the second preparation, proceeding the same as for the cyanide of silver. *To prepare Cyanides of Copper and Zinc.*—For copper, dissolve 1 oz. of sulphate of copper in 1 pint of hot water. For zinc, dissolve 1 oz. of the sulphate of zinc in 1 pint of hot water, and proceed the same as for cyanide of silver. The electro-plater, to insure success in plating upon all metals and metallic alloys, must have two solutions of silver; the first to whiten or fix the silver to such metals as iron, steel, Britannia metal, and German silver, the second to finish the work, as any amount of silver can be deposited in a reguline state from the second solution. *First, or Whitening Solution.*—Dissolve 2½ lbm. (troy) of cyanide of potassium, 8 oz. carbonate of soda, and 5 oz. cyanide of silver in one gallon of rain or distilled water. This solution should be used with a compound battery, of three to ten pairs, according to the size of the work to be plated. *Second, or Finishing Solution.*—Dissolve 4½ oz. (troy) of cyanide of potassium, and 1½ oz. of cyanide of silver, in 1 gallon of rain or distilled water. This solution should be used with one large cell of Smee's battery, observing that the silver plate is placed as near the surface of the articles to be plated as possible.—N.B. By using the first, or whitening solution, you may insure the adhesion of silver to all kinds of brass, bronze, red cock metal, type metal, &c., without the use of mercury, which is so injurious to the human system. *To prepare a Solution of Gold.*—Dissolve 4 oz. (troy) of cyanide of potassium, and 1 oz. of cyanide of gold, in 1 gallon of rain or distilled water. This solution is to be used warm (about 90° Fahr) with a battery of at least two cells. Gold can be deposited of various shades to suit the artist, by adding to the solution of gold a small quantity of the cyanides of silver, copper, or zinc, and a few drops of the hydro sulphuret of ammonia.

ELECTRO-PLATING BATH. See CYANIDES.

ELECTRO-SORTING APPARATUS.—M. Froment has devised an apparatus for the separation of iron from matters by which it may be accompanied. The apparatus consists of a wheel carrying on its circumference eighteen electro-magnets. The iron ore reduced and pulverised is spread continually upon one of the extremities of a cloth drawn along with it, and passed under the electro-magnets in motion. The iron in the ore which has of course been brought into a magnetic state by any of the processes by which this may be effected, is separated by the magnets, and the impurities carried onward. See *De la Rue's Electricity*.

ELECTRO-TELEGRAPHY. The simultaneous appearance of the electric spark at the respective ends of a long conducting wire forcibly attracted the attention of electricians in the early days of the science.

A series of remarkable experiments were made by Dr. Watson, commencing on July 14th, 1747; when he passed an electric discharge from the Thames bank at Westminster to the opposite bank at Lambeth, by means of a wire suspended to Westminster Bridge. He continued his researches; and, on August the 5th of the following year, he arranged 12,276 feet of wire at Shooter's Hill, the beginning, the middle, and the end of which were led into the same apartment. He found out that the electric signs at the middle of the wire coincided in time with the discharge at the two ends, proving that the passage, at least in such a length of wire, was instantaneous. In reference to these results Professor Muschenbroek wrote to Dr. Watson, "Magnificimus tuis experimentis, superasti cunctas opiniones."

The idea of applying this property to the transmission afar of telegraph signals proper was an early and natural result of these discoveries. But many onward steps were necessary before the idea could assume any definite form; and further advances in knowledge were essential before the idea could be realised.

It would far exceed our limits were we to attempt the most hurried sketch of the history of this art; we shall therefore content ourselves with illustrating the leading doctrines, that have been realised in the telegraph systems which are most in favour at the time in which we write.

Jacked up, as it were, in all bodies, is a large store of electric force, the equilibrium of which is disturbed in a greater or less degree by a variety of causes, some extremely simple, others more complex; and, according as one or other cause is in operation,

the conditions under which the electric force is manifested vary; some conditions being very unfavourable, and others very favourable to the object in view.

Friction is a well known means of producing electric effects. Amber (in Greek *electron*) was the first substance on which they were noticed in a special manner, and hence the name. Light bodies, such as gold leaf, or feathers, are attracted by rubbed amber, the leaf gold is quickly repelled again, the feathers not so readily. In due course it was discovered that this difference of behaviour is due to the *conducting* electricity, and the feathers not so; the one allowing the force to diffuse itself about it, the other receiving and retaining it only in or near the points of contact; if the former property were universal it would be impossible to collect electricity; if the latter, it would be impossible to get rid of it. *Conduction* is well illustrated and turned to useful account in the iron and copper wires, by which distant telegraph stations are connected with each other; *insulation*, by the glass or porcelain articles with which the said conducting wires are suspended to the poles above ground, and by the gutta percha with which the subterranean or submarine wires are covered.

The rapidity with which electric force traverses conductors depends upon the circumstances under which the conductors are placed; in one case, as in that of wire suspended in the air, the electric force has little else to do than to travel onward and be discharged from the far end of the wire; in the other case, as in that of buried wire, it has to disturb the electric equilibrium of the gutta percha as it travels onward, and thus suffers considerable retardation. The greatest recorded velocity of a signal through a suspended copper telegraph wire is 1,752,000 miles per second, by M. Hipp; the lowest velocity through a buried copper wire, 750 miles per second by Faraday. Intermediate velocities are recorded, for which the nature of the wire or the conditions under which it was placed were different. Wheatstone found the velocity of electricity under different conditions from the above to be 28,000 miles per second. His wire was copper, and was wound on a frame. The electricity that was employed by Mr. Wheatstone in these experiments was obtained from the friction of glass against an amalgam of tin. The various velocities are due partly to the conditions under which the conducting wire is placed, and partly, no doubt, to the varied properties of electricity from various sources. And the very different methods of measuring off the velocities in this and in other cases may have an influence over the respective values.

Electricity is obtained from other sources than friction with so much greater facility, and in forms so much more applicable and manageable for telegraphic purposes, that frictional electricity has not been applied in real practice. It must not, however, be passed over in this place, because one of the earliest telegraphs, perhaps the very first in which a long length of wire was actually used, was actuated by this form of electricity. In 1816 Mr. Ronalds established, in the grounds attached to his residence at Hammer-smith, eight miles of wire suspended by silk to dry wood, besides 175 yards of buried wire to glass tubes embedded in pitch and enclosed in troughs of wood. He obtained his electricity from a common electrical machine, and his signals from the motion of light bodies, balls of elder pith, produced under circumstances analogous to those to which we have already referred. At the far end of his telegraph wire two pith balls were suspended close together. Electricity applied at the home end of the wire at once diffused itself throughout the conducting system, including the pair of light balls. Just as we have seen gold leaf recede after having approached rubbed amber, and acquired an electric charge; so the pith balls, each being charged with electricity, derived from the same source, recede from each other; and thus in obedience to the fundamental laws of static electricity, for which we must refer readers to treatises on the subject. Here, then, we have one solitary signal. The manner in which Mr. Ronalds turned it into language was ingenious. He pressed time into his service, and by combining time and motion he obtained a language. He provided a clock movement at each station; the clocks were so regulated as to be synchronous in their movements; each of them carried, in lieu of a hand, a light disc, having the letters of the alphabet and other signals engraved on it. The disc was hidden by a screen, in which was one opening. It is obvious that if the clocks were started together, and had uniform rates, the same letter at the same time would be visible through the opening in each screen, and letter by letter would pass seriatim and simultaneously before the respective openings. If absolute uniformity is difficult for long periods, it is practicable for shorter. The sender of a message watched the opening of his screen; the moment the letter approached that he desired to telegraph he charged the wire with electricity, and the balls at the far station moved; the letter then visible there corresponded with the one at the home station, and was read off. The sender watched till the next letter he required came round, and so on.

Let us now pass on to some of the leading features of electro-telegraphy, as it has

been realised of late years, and in a description of some of the telegraph instruments that are most in use.

Chemical action is the most fertile source of electricity. If a silver fork and a steel knife are connected together by a piece of wire, and the fork is thrust into a piece of meat, say a hot mutton chop, the moment an incision is made in the meat with the knife, electricity will pass along the wire, and continue to do so while the above disposition of things remains. Upon the proper test being applied, the electricity is readily detected. This is the *current form* of electricity. The amount of force in circulation in this particular combination is not very great, and its power of travelling to a distance is not very high, but still it is quite capable of producing good signals, on a delicate arrangement of the needle instrument (of which more hereafter) with which in England we are so familiar.

The amount of electricity obtained by means of chemical action, is increased to the required extent by a judicious selection of metals, and of the liquid or liquids in which they are immersed. Zinc is invariably used as one of the metals; it is represented by the iron of the knife in the above experiment. Copper, silver, and platinum or graphite (i.e. carbon) is selected for the other metal. When the two metals are immersed in a same liquid, a mixture of sulphuric acid with salt water or fresh, is employed. When two liquids are used, they are separated by a porous partition; the zinc is usually placed in the sulphuric acid solution, and the other metal in a solution varying with the nature of the arrangements proposed. Zinc is naturally soluble in the acid solution in question; and would therefore waste away and be consumed at the expense also of the acid, unless precautions were taken to make it resist the ordinary action of the solvent. When zinc is dissolved in mercury it is not attacked, under ordinary circumstances, by sulphuric acid solution. Hence the plates of zinc employed in all good voltaic combinations, as they are called, into which this acid, in a free state, enters, are protected by being well amalgamated. That is, they are dipped in a strong acid mixture and well washed; and are then dipped into a mercury bath, and are placed aside to drain. The operation is generally repeated a second time; and, in the best arrangements, the further precaution is taken of standing the zinc plate, while in the acid water, in some loose mercury, placed either in the bottom of the containing vessel, or in a gutta serena cell; by the latter arrangement, mercury is economised. In single liquid arrangements, it is desirable to select a metal that is not attacked by the acid. Copper has been extensively used, and is a very valuable; but it possesses the defect of being slowly attachable. The waste, however, that it suffers in itself from this cause, is of small moment compared with the certain secondary results, which terminate in the consumption of the acid and the zinc, and the destruction of the functions of the apparatus. Gold or platinum are free from these defects, but are too costly. Silver, is to a great extent free from them, and has been much and successfully used, especially when platinised, that is, having its surface covered with finely divided powder of platinum. The corrosion from gas retorts, cut into plates, and similarly treated, forms with amalgamated zinc one of the cheapest and most effective combinations.

A single pair of plates, no matter what their character, is unable to produce a force that can overcome the resistance of a wire of any length, and produce an available result at a distant station; and hence a series of pairs are employed in the telegraphic arrangements. A (fig. 704) represents a common mode of arranging a series of pairs of plates. It consists of a wooden trough made water-tight, and divided into water-tight cells. The metals are connected in pairs by copper bands; each pair is placed astride over a partition, and all the zincs face one way. When the plates (copper-zinc) are placed in, and the cells are filled up with pure white sand, and the acid water poured in, we have the very portable battery that was originally used by Mr. Cooke, and is still much employed in England. When batteries of a higher class are employed, the cells are distinct pots or jars; and great precautions are taken to prevent any communication existing between the neighbouring cells, save by means of the copper band. In the trough form there is a leakage and loss of force from cell to cell. The zinc or copper is the positive end of each a series, and the zinc, the negative; and both are in a condition to discharge, either each to the other, by means of a wire, led from one to the other, or each to the earth, one by a wire leading to the earth at the place where the battery stands, and the other by a long wire (say a telegraph wire), leading to the earth at a distant place. The resistance to be overcome is, in the former case, low; and the current of force in circulation is proportionately greater. Under whatever circumstances a wire takes part in promoting the discharge of an apparatus of this kind, the whole of the said wire is in a condition to indicate the presence of the force that is pervading it; and as the force may be presented to the wire in either of two directions, that is to say, the copper or the zinc, namely, the positive or the negative end of the battery, may be presented to the given end of the

telegraph wire, the relative condition of the wire will be modified accordingly. Not only can the direction of this current force be inverted at pleasure, but it can be

704

maintained for any length of time, great or small, and in either direction. This is accomplished by various mechanical arrangements, which are the keys, commutators, or handles of the various telegraph instruments (of which more hereafter), and are often the only part presenting any complexity about them. In *fig. 704*, the source of electricity, *i.*, we have already described; this test-instrument for the abnormal state of the wire, that is to say, the telegraph proper, is the part *A*. The complex part, consisting of springs, cylinders, and studs, shown below *A*, is nothing more than the necessary mechanical arrangement for directing at pleasure the current from the battery *x*, in either direction through the wire, and through the part *A*. By following

the letters in the order here given, the course of the current may be traced from its leaving, say the positive or copper end of the battery, till its return to the zinc or negative end; *c r' d w w c a z' b n z*. If a companion instrument were in any part of the circuit of the wire *w w*, it would correspond in its signals with the same instrument, *fig. 704*.

One of the properties possessed by a wire, during the act of discharging a voltaic battery, is to deflect a magnetised needle. If the two are parallel in the normal state of the wire, the needle is deflected this way or that, when the wire is in the abnormal state; and if the needle is very delicate, and a large enough amount of electricity be circulating through the wire, the needle reaches the maximum deflection of 90°. This is an extreme case, and cannot be approached in practice. Indeed, the deflection of any ordinary needle, under the action of an ordinary telegraph wire, would not be appreciable. But, as every foot of the wire has the same amount of reaction, we have merely so to arrange the wire that many feet, — a long length of the wire, shall be made to react upon the needle at the same time, and thus the effect is multiplied in proportion to the length of wire so concentrated. This is managed by covering a considerable quantity of fine wire with silk or cotton, and winding it on a frame (*fig. 704*), suspending the needle within the frame. Such an instrument is called, from its properties, a *multiplex*. It is seen at a glance that the wire of the multiplier is an addition over and above the length of the actual telegraph wire required for reaching the distant station, and thus it practically increases the distance to be traversed: its smallness adds to this. The multipliers commonly used add a resistance equal to six or seven miles of telegraph wire.

Let us now turn to the face of the instrument. Here we have a dial and an index, which is on the same axis as the magnetised needle above described, capable of being deflected to the right or left, and limited in its motion by ivory pins. We have a handle for working the mechanical part so connected that, as it moves to the right, it directs a current into the wire such that the needle moves to the right, and vice versa.

An alphabet is constructed from the combination of these two elementary motions, *i.e.* or more of either or both kinds of deflection being used for the various letters, as shown on the engraved dial. This is Cooke and Wheatstone's single needle instrument, *fig.* 705.

The form and character of their double needle instrument is shown in *fig.* 706. It is precisely a duplicate of the former; two handles, and their respective springs, studs, and cylinders, two multipliers, and two magnetised needles, with their external indexes, and two telegraph wires. One battery, however, is sufficient. One or more of either or both kinds of deflection of either or both needles, according to the code engraved on the dial, constitutes the alphabet. This instrument is very extensively employed; messages are sent by it with extreme rapidity.

Another property possessed by a wire conveying a current is that of converting soft iron, for the time, into a magnet. The attractive power, which can thus be given to, and withdrawn from, the soft iron at pleasure is turned to useful account, either in producing direct mechanical action, or in liberating the detents of a clock movement. Here also the effect of the

solitary wire is insupportable, and many convolutions around the iron are necessary in order to obtain a useful result.

The simplest application of this principle is shown in *fig 707*. Here are two brass

707

reels, filled with cotton-covered copper wire in one length. They are hollow, and a U-shaped bar of iron passes through them, presenting its ends at the face turned toward us in the drawing. This bar becomes magnetic, — forms what is called an *electro-magnet* every time and as long as an electrical current circulates in the wire; and its ends become respectively north and south poles. A narrow plate of iron, an *armature*, as it is termed, is mounted on pivots in front of the ends or poles of the magnet; it carries a vertical stem upon which the hammer is fixed. Every time the

iron bar is magnetic the armature is attracted, and the hammer strikes the bell. The spring or contact maker for introducing the current of electricity into the circuit, is shown in front on the right hand side. This is Mr. Walker's bell for signalling railway trains from station to station. The language consists of one or more blows. One, two, and three blows are the signals for common purposes, half a dozen blows is the limit. The acknowledgment of a signal is its repetition. By a simple arrangement of an index, that moves in fellowship with the hammer, the eye, as well as the ear, may read the bell signals.

Fig. 708 shows another application of the direct action of an electro-magnet in pro-

708

ducing telegraph signals. It is Morse's printing telegraph, very generally used in America, and used to no small extent in Europe. The coils of wire are shown at *m*, the armature at *n*, fixed at one end of the lever *p*, which is itself carried on centres at *c*. The range of motion here is small in order to produce rapid utterance; it is regulated by the screws *d* and *i*. The reaction of the spiral spring *f* restores the lever to its normal position each time the magnetism ceases. The signals consist of dots or dashes, variously combined, made by the pointed screw *t* upon the slip of paper *p*, running from the drum at the right in the direction of the arrows; a few such signals are shown upon the end of the paper slip. We have described the telegraph proper, which is seen to be extremely simple. The only parts at all complex are, as with the needle instruments already described, the mechanical parts, namely the train of wheels for carrying on the paper band, and the key or contact-maker, not shown in the figure. The amount of pressure required from the point *t* in order to produce a

mark, in such that it cannot conveniently be produced by the magnetic attraction, derived from a current of electricity that has come from a far distant station in order to circulate in the coils of wire π . This difficulty does not prevail in the signal-bells *fig. 707*, which are, at most, not required to be more than eight or ten miles apart, and in which also momentum can be and is accumulated so as to conspire in producing the final result. Morse has, therefore, had recourse to a relay, as he calls it. This, in principle, is pretty much the same thing as the instrument itself; but it has no heavy work to do, no marks to make; it has merely to act the part of a contact-maker or key; it can hence be made very delicate, so as to act well by such currents as would not produce any motion in the instrument itself. The batteries which furnish the electricity for doing the actual printing work in Morse's telegraph, are in the same station with the instrument itself. The office of the relay is to receive the signals from afar, and to make the necessary connections with the local battery and instrument so as to print off the signals on the paper in the usual way. It is obvious that the motions of the instrument and the relay are sympathetic, and that what a trained eye can read off from the one a trained ear can read off from the other. The relays are constructed with much finer wire than is required for the instrument itself, so that the current circulating in them, although very low in force, is multiplied by a very high number, and becomes equal to the delicate duty required of it.

Fig. 709 is another illustration of the direct application of the electro-magnet without

709

adventitious aid. It represents a detent of McCallum's Globotype for recording signals. The long tube contains small glass balls, which are retained therein by a detent attached to the armature of an electro-magnet. Every time the armature is attracted the ball is liberated and runs down into a grooved dial, where it remains for inspection. One or more tubes and detents are used, according to the nature of the signal required. As applied to the signal bell (*fig. 707*) three tubes are used; one charged with black balls, for indicating the number of bell strokes made; one with white balls, for indicating the bell signals sent; one with spotted balls, for marking off the time in quarters of hours or intervals of less length. The balls, when liberated, all run into the same dial and arrange themselves serialim.

710

We may here refer to the case of another bell or alarm, in which the magnetic attraction derived from the current that arrives, is not equal to the mechanical work of striking a blow and sounding a bell; but which is able to raise a detent, that had restrained a train of wheels; and so allow the mechanism of the latter to do the work required. This arrangement is shown in Cooke and Wheatstone's alarm, *fig. 710*; t is the bell; m is the double headed hammer, which is in fact the pendulum, attached to the pallets f , which work in a scape-wheel hidden in the figure, and in gear in the usual way with a coded spring in the box b , by the train r, r_1, r_2, r_3 . The electro-magnetic part here, as in other instruments, is simple enough; w is a lever moving on a centre above l , having at one end an armature a , facing the poles of the electro-magnet e ; and at the other end c , a hook which faces the wheel r , and by catching in a notch on its circumference, keeps the train at rest. But when a current circulates through the coils e , the armature is attracted, the hook is raised, the train is liberated, and the pendulum-hammer vibrates and strikes a succession of blows. π is a support carrying a small spring, which reacts on the lever, and restores

it to its normal position when the magnetism ceases. This alarm is used for calling the attention of telegraph clerks. It requires a little attention to keep up the proper adjustment between the spring on the one hand, and the magnetic attraction on the other.

The telegraph originally adopted and still largely used by the French Administration, is somewhat akin to the alarm just described. It has a train of wheels, a scape-wheel with four teeth, and a pair of pallets. There is, however, no pendulum; but the pallets are connected with the armature of an electro-magnet, in such a manner that, for each attraction or repulsion of the armature, the scape-wheel is liberated half a tooth; for an attraction and a repulsion a whole tooth; so that four successive currents, producing of course four consecutive attractions and repulsions, produce a whole revolution of the scape-wheel. The axis of the latter projects through the dial of the instrument (fig. 711) and carries an arm *a* or *b* (fig. 712), which,

711

following the motion of the wheel, is able to assume eight distinct positions. The apparatus is generally double, as shown in the figure; and the signals are made up of the various combinations of the eight positions of each of the two arms. The arm is half black, the other half white. The position of the black portion is read off; the white portion is merely a counterpoise. When only one half of the dial, or one index is in use, the combinations are shown by producing with the one index successively the positions of the two, whose combination makes the signal, always giving first the position of the left hand index, then that of the right. The handles shown in front are the contact-makers; and are so constructed that the position of the arm on the dial coincides with the position given to the handle. Fig. 712 is a front view

712

of the two arms; part of the dial is supposed to be removed, so as to expose the four-toothed wheel already mentioned, and the pallets *x* and *z*; which, in their movement to and fro, allow of the semi-tooth advances of the wheel.

In these various applications of the electro-magnet, the armature has been of soft iron, and the only action of the electro-magnet has been to attract

it. It has been withdrawn from the magnet after the electricity has ceased to circulate, either by its own gravity, by a counterpoise, or by a reacting spring. We now come to a telegraph that is well known and much used, *Henley's magneto-electric telegraph*, in which there is no reacting spring; and in which the movement or signal is produced by the joint action of attraction and repulsion; and the return to its normal state by the same joint action. Each side of *Henley's* electro-magnet has a double instead of the single termination, that we have been considering in all preceding cases. A piece of soft iron, like a crescent, is screwed upon each of the poles; the horns or cusps of the respective crescents are facing and near to each other; and a magnetised steel needle is balanced between them. This arrangement is somewhat like the

following (|). So long as no current is circulating in the coils of the electro-magnet, the crescents are impassive soft iron, and no one point of either of them has more tendency than any other point to attract either end of the magnetised needle that is between them. But while a current is circulating, one of the crescents is endowed with north magnetic polarity, which is especially developed at its horns, and the other with south polarity. Suppose the horns of the right hand crescent are north poles, those of the left south poles, and the top end of the needle is north. Four forces will conspire to move the needle to the left. Its top will be attracted by the left hand crescent and repelled by the right; its bottom will be repelled by the left, and attracted by the right. When this current ceases to circulate, the simple attraction between the magnetised needle and the soft iron of the crescent tends to retain it in a deflected position. This tendency is increased by a little residual magnetism, that is apt to remain in the best iron, notwithstanding every care in its preparation. In order, therefore, to restore the needle to its normal position, a short quick current in the reverse direction is given. These instruments are single or double. Only one kind of deflection of the needle is available for actual signals; the other motion being merely the return to the normal state. The single needle alphabet is composed of deflections of a short or a long duration; these are produced by holding on the current for an instant or for more than an instant; and the various combinations of short and long correspond to Morse's dot and dash system. The double needle alphabet consists of combinations of the deflection of either or both needles.

Fig. 713 shows Healey's instrument, and, in completing the description of it, we have

713

to describe another source of electric current to which no allusion has been hitherto made. The electricity here employed is obtained neither by friction nor by chemical action, but by means of magnetism and motion. If a piece of metal is moved in the presence of a magnet, or a magnet is moved in presence of a piece of metal, a current of electricity is generated in the metal. The results are multiplied when the metal is a coil of covered wire; so that we have here the converse of the electro-magnet; in the one case electricity had produced magnetism, in the other magnetism produces electricity; hence the name *magneto-electric* telegraph. We have here a powerful set of steel magnets, all the north ends pointing in one direction, and bound together with a plate of iron, and all the south ends similarly arranged in the other direction. Facing each end, but not quite in front when at rest, is an electro-magnet proper, *n*, *n*, consisting of the U-shaped iron rod and the coil of covered wire, as described in fig. 707. Each electro-magnet is mounted upon an axis. *c* is a short lever or key; on depressing this the electro-magnet moves from its normal position in a region of lesser magnetic force, into a new position in the region of greatest magnetic force, and thus is the double condition, enunciated above, complied with; the copper wire is moved in the presence of a magnet, and thus under the most favourable conditions; and the U iron, rising from a few to a strong magnet, its lines of magnetic force move in presence of the copper wire. Just as a current, arising from a long distance, had to be revolved in Morse's arrangement (fig. 708) in an electro-magnet of a long coil of fine wire, so as to be much multiplied in order to do its work, so here a magneto-electric current, that has to be sent to a long distance, must be generated in a long coil of very fine wire in order to have electro-motive force sufficient to overcome the resistance opposed to it. In like manner the electro-magnets of the instrument *n*, in which it is received at the far-off station, have the same multiplying characteristics. The magneto-electric current exists only during the motion of the electro-magnet in front of the steel magnets, and this motion must be rather brisk, or the change of place is slow and the current feeble; but the current ceases with the motion. The needle, however, remains deflected from causes to which we have already referred, and if the hand is raised gently, so that the coils return

slowly to their normal position, the needle will remain deflected; but, if the hand is so removed that the coils return quickly from the region of greatest to one of lesser magnetic force, a reverse current of lesser force than the original is generated, which releases the needle from its deflected position and restores it to its normal place, ready for making the next signal. In a recent form of this instrument Mr. Henley has obviated the necessity of moving the electro-magnets, still retaining the same fundamental principles. He uses a set of large U-shaped permanent magnets, and places the electro-magnet in the space between the branches of the permanent magnet, and so that the four poles of the two magnets, the permanent and the electro, shall be flush with each other or in the same plane. A couple of iron armatures are inserted on a disc in front of the magnets. The disc has a motion on a centre: the armatures are curved or crescent-shaped. Their form is so adjusted to the relative positions of the poles of the respective magnets that, in their normal or ordinary position, one crescent connects the N. pole of the magnet with one, say the *upper*, pole of the electro-magnet, and the other crescent connects the S. pole of the permanent magnet with the *lower* pole of the electro-magnet. On pressing a key the disc moves, and the armatures so change in position that the N. pole of the magnet is connected with the *lower*, and the S. pole with the *upper* poles of the electro-magnet. By this arrangement the polarity of the electro-magnet is reversed at pleasure, and in its transition from being a magnet with poles in one direction, to becoming a magnet with poles in the reverse direction, an electric current is generated in the wire with which it is wound, and the direction of the current is this way or that according as the transition is from this direction of polarity to that. This form of magneto-electric machine allows of larger electro-magnetic coils being used, and gives the manipulator comparatively very little weight to move in signalling.

We have shown how an electric current generates magnetism, and how magnetism generates another electric current; it would follow logically that one electric current should therefore generate another electric current; for the magnetism produced by a current circulating in one wire, must have all the properties of magnetism, and among them, that of producing another current in another wire, and so it is. A few convolutions of a large sized wire are coiled round an iron rod; and outside the larger wire is a very great length of finer wire. The current from the battery is called the *primary* current in this arrangement; and the moment it begins to circulate in the large wire, it magnetises the iron and generates a current, called *secondary*, in the fine wire, which is able to penetrate to a very great distance. When the primary current ceases, magnetisation ceases, the lines of magnetic force disappear, and a reverse secondary current is produced. This was the method proposed for obtaining the secondary current for traversing the Atlantic Ocean from Ireland to Newfoundland. The large wire is not necessarily first coiled on; in the coils for the Transatlantic telegraph it was coiled outside. Nor is the presence of iron essential to obtaining secondary currents.

It will have been noticed in all the arrangements which have hitherto been described, that the signals are produced by motions,—that the electric current on reaching the far station is multiplied by being directed through many convolutions of wire, and is made to act upon either a piece of soft iron or a piece of magnetised steel, and to move them, the motion being turned to account directly, or by the intervention of mechanism. We have yet another property of electricity, that has been very successfully applied to the production of telegraphic signals by Mr. Bain, in his electro-chemical telegraph. If a current of electricity is led into a compound fluid body, say into water by one wire and out of it by another wire, the body is decomposed into its constituent elements, one of which, the oxygen in the case in question, makes its appearance at one wire and the other—the hydrogen makes its appearance

714

at the other wire. The same holds good with bodies of a more complex character in solution in water. The compound selected by Mr. Bain is cyanide of potassium. With a solution of this, he saturates a long ribbon of paper, similar to that employed in Morse's telegraph. He causes the paper *n* (fig. 714) to pass over a drum of brass *a*, between the metal of *a* and an iron point or stylus *r*. The electric current enters the apparatus by the point *r*, passes through the solution of cyanide of potassium, with which the paper *n* is saturated, and out by the

spring *r'*, which is in metallic contact with the drum *a*. Decomposition takes place and the well known cyanide of iron (Prussian blue) is formed at the point of contact

of the iron stylus *r* with the paper, the iron of the compound being supplied by the stylus itself. The paper is carried on by ordinary mechanism; and a dot and dash alphabet is formed, according to the duration of contacts at the sending station. There is a single wire and a double wire code, and the signals appear as deep blue marks upon the paper. Supplies of paper saturated with the solution are kept in reserve. This is unquestionably a telegraph of extreme simplicity. It has been employed with much success.

Mr. Whitehouse prepared for the Atlantic Telegraph a system in which motion and chemical action each play their part. The secondary currents that he employed were not able to produce the chemical decomposition that he requires for his signals. He therefore received them in a very sensitive relay, either an electro-magnet or a multiplier. The relay was a contact-maker, and connected the necessary number of local batteries with the printing apparatus, which consists of a ribbon of paper, saturated with a chemical solution and passing between a drum and a steel point.

We should exceed our limits, were we to attempt the description of some of the many other forms that have been proposed. The above are good illustrations of the leading principles, and are all in successful use. Some telegraphs will print in ordinary character; this result is only attained by much complexity; and its value is more than questionable, it being as easy to learn a new code as a new alphabet; and telegraph clerks read their signals as readily as they read ordinary writing or printing, and they acquire their knowledge in a very short time. Hence probably it is that telegraphs to print in ordinary characters are but little known in real practice; nevertheless, some very promising instruments of the class have been produced, by House, and especially one more recently by Hughes, both of the United States. The following table has been drawn out as an illustration of the codes of some of the chief instruments that have been the subject of this article. It shows the number and nature of the signals (deflections, dots, dashes) for producing the name of the great discoverer of electro-magnetism, which is the foundation of electro-telegraph. The figures on the right are the number of marks or signs in printing and in each kind of telegraph.

The *Rheo-electro-static* system of telegraphy was first described by M. Biot, in 1849. It is applicable to some but not to all forms of telegraph. It has been applied on the South Eastern Railway to the signal-bells (fig. 704), for the purpose of reducing the amount of battery power required under other circumstances to be maintained. The wire, by which a pair of bells are connected, is in its normal state in permanent connection with the similar pole, say the positive, of batteries of equal power at the respective stations, so that two currents of equal power are opposed to and balanced against each other. Under these circumstances, the wire is in a null, or *rheo-electro-static* state; neither current circulates. If the connection of one of the batteries is reversed, so that its negative pole is presented to the wire, then the currents of both batteries are in the same direction, and they circulate as one current, equal in value to the combined force of the two batteries. The application is obvious; that, whereas, under the ordinary system, a *whole* battery, of force sufficient to traverse the distance and do effective work, must be at each station, under this system only *half* each battery is necessary at each station, for producing the same effective work. Also, if a *half* more battery power is placed at each station than is necessary for the actual work

required, signals of higher power are obtained under common circumstances; and also the equilibrium of the two opposite currents may be disturbed at any place between the two stations, and signals may be made by merely making a connection between the line-wire and the earth; because the negative pole at each station is fitted up in permanent connection with the earth, and, as the positive poles are in like connection with the line-wire, each battery current is made to circulate through its own signal-bell every time the earth and line-wire are placed in connection. By this means the guard of a train can make signals of distress to the nearest station without the aid of portable apparatus. Considerable care is required to obtain good communication with the earth on the open railway for making distress signals, or otherwise the discharge is imperfect, and no signal is made. Fish-baited rails are very valuable for this purpose; in their absence, especially at embankments, metal must be buried for the purpose at intervals in the moist earth, and a wire attached for use. Contact springs on the telegraph poles are proposed.

715

Telegraph wires are suspended to poles by insulators of earth-ware, glass, or porcelain; the material and shape varying according to the experience of the engineer and the length of line to be insulated. In very short lengths, the battery power required for overcoming the resistance is not great; it will therefore not overcome the resistance of an insulator of moderate quality, and escape to the pole and thence to the earth; but the battery power required to overcome the resistance of very long lengths of wire is equally able to overcome the resistance presented by inferior insulators, and to escape in considerable quantities at every pole; so that the force which reaches the far station would not be equal to its work.

716

It is for these long lines that the greatest ingenuity has been expended in constructing insulators. Fine porcelain is most in favour from its presenting a very smooth surface, and being less hygroscopic than glass; and it is distorted into most mysterious-looking shapes in order to present as great a distance, and one as much sheltered as possible, between the part, with which the line-wire is in contact, and the part that is in contact with the pole.

For subterranean and submarine wires still greater care is necessary, because they are in the very bosom of the earth or sea, to which the current will escape, when and where it can, in order to complete the discharge. Fig. 715 represents the cable that has been lying in the British Channel between Dover and Calais, since September, 1851. It contains four No. 16 copper wires, each wire is doubly covered with gutta-percha. The four wires are then twisted into a rope; and the rope is thickly covered, first with hempen yarn, tarred, and finally with a jacket of ten No. 1 iron wires. The cable is shown in perspective and in section. Fig. 716 shows the perspective and section of the Irish, a single wire cable. It consists of a small central conductor, of one No. 16 copper wire, doubly covered with gutta-percha, then with hempen yarn as before; and finally with a protecting jacket of ten No. 2 iron wires. The

Calais cable weighs 7 tons per mile; the Irish, 2 tons per mile. The Atlantic

telegraph cable, of which nearly 3000 miles were prepared, is in section, just the size of a silver threepenny piece. It is a single wire cable, the wire was a strand of seven No. 22 copper wires, trebly covered with gutta percha, then with yarn, and protected with eighteen strands of seven wires each, of No. 22 iron wire. It weighs 19 cwt. to the mile. This cable is lost. The iron jacket is in disrepute now for deep sea cables. Hemp is preferred.

Telegraph signals pass with far less rapidity through buried and through submarine wires, than along the ancient aerial wires. The slow travellings mentioned above, were through wires of this kind. We must refer to treatises on Electricity for full details of the conditions presented by a telegraph cable. In practice it is found that on first sending a signal into a submarine wire, the electricity is delayed on its road, in order to produce a certain electrical condition upon the surface of the gutta percha that is in immediate contact with the conducting wire. Nor is this all; before a second distinctive signal can be sent, it is necessary that the condition produced by the first signal shall be destroyed; and this is an operation, requiring even more time than was consumed in the mere act of producing it. These two classes of retardation, especially the latter, were largely manifested in the Atlantic cable; and have called forth all the ingenuity of electricians, in order to mitigate or to modify them.—C. V. W.

ELECTRUM, or ELECTRON. The ancient Electrum was an alloy of gold with $\frac{1}{2}$ part silver. The Electrum of Kalpruth is gold 64 silver 36. The ancient name of amber. The modern Electrum is an alloy of copper, zinc, and tin, with sometimes nickel.

ELEMENTS. See EQUIVALENTS, CHEMICAL.

ELIUM. This appears to be the resinous product of various terribunthaceous trees. The Edinburgh College, states it to be a "concrete resinous exudation from one or more unascertained plants." And the London Pharmacopœia describes it, as a concrete turpentine derived from an unknown plant. In the former edition *Amgris Elmifera* was named as the plant producing this resin. This error was due to Linnaeus, who confounded under one name two distinct plants. The larger quantities of Elium come to us from the Dutch settlements through Holland. It is imported in "the lump," and in masses weighing from one to two pounds each enveloped in a palm leaf.

Bonastre gives the constituents of Elium:

Volatile oil	-	-	-	-	-	12.5
Resin soluble in hot and cold alcohol	-	-	-	-	-	60.0
Resin soluble in hot but not in cold alcohol	-	-	-	-	-	24.0
Bitter extractive	-	-	-	-	-	2.0
Impurities	-	-	-	-	-	1.5

The resin soluble in cold alcohol consists according to Johnston of $C^{11}H^{10}O^1$, while the latter (*Elimine*) is composed of $C^{11}H^{12}O^1$.

Elium is employed in making lacquer. See VARNISH.

ELIUTRIATE. (*Seutrier*, Fr., *Schlemmen*, Germ.) When any insoluble powder such as chalk is diffused through a large body of water, and then allowed to subside slowly, of course the larger particles will by their gravity be the first to subside. If then the supernatant liquor is poured off, or better, if drawn off by a siphon, the finer powder will be collected in the next vessel; and by repeating this process an impalpable powder may be obtained. This process is called *Eliutration*.

ELEPHANTS' TUSKS. See IVORY.

ELIASITE. An ore of Uranium, a mineral allied to pitch blende, but differing from it widely in its large proportion of water and lower specific gravity (4.026 to 4.237).

It occurs with fluor, dolomite, quartz, &c., at the Elias mine, Joachimsthal, in large flattened pieces, sometimes half an inch thick, of a dull reddish-brown colour, approaching to hyacinth-red on the edges.

It is subtranslucent, with a greasy unvitreous lustre, and affords a dull streak, varying from wax-yellow to orange. Hardness between calcite and fluor spar.

It is composed of Peroxide of Uranium	-	-	-	-	-	61.33

						<hr/> 99.70

Before the blowpipe it affords a reaction like pitchblende. Decomposed by muriatic acid. — H. W. B.

LINXIR OF VITRIOL, a preparation of sulphuric acid, with some aromatics.

ELM (*Ulmus*, *Orme*, Fr.; *Ulm*, Ger.) Of this European timber tree there are five species. The *Ulmus Campestris*, the English Elm, is regarded in this country as one of the finest of European deciduous trees for park scenery; it lives for upwards of 200 years, forming a remarkably straight tall trunk. The quality of timber depends a good deal on the soil in which it is grown, being always best on a dry, loamy soil, and plenty of air. The *Ulmus montanus*, the Mountain-Scots or Wych Elm: the trunk is not so lofty nor the wood so heavy as the English Elm; and though coarsely grained is very highly prized by shipbuilders and cartwrights. It possesses great longitudinal adhesion, and is consequently one of our stiffest and straightest timbers. These woods are not liable to split, and bear the driving of nails or bolts better than any other timber, and are exceedingly durable when constantly wet. They are therefore much used for the keels of vessels, and for wet foundations, waterworks, piles, pumps, and boards for coffins. On account of its toughness it is selected for the naves of wheels, and for the gunwales of ships.

ELVANS. Granitic and felspathic porphyritic rocks, which are frequently found traversing both the granite and slate rocks.

"The Elvans or veins of quartziferous porphyry, that is, a granular crystalline mixture of felspar and quartz which are common both in Cornwall and Devon, and near the granite of the south-east of Ireland, are probably in reality granite veins, or veins proceeding from a granitic mass." — *Jukes*.

"When these granite-veins are of a large size they are termed *Elvan courses*; indeed this is the only distinction between these two forms of elongated masses of granitic rock. In composition these elvans are either short-rock, eucrite, felsparite, or even varieties of fine-grained granite." — *Dease*.

EMAIL OMBRANT, a process which consists in flooding coloured but transparent glazes over designs stamped in the body of earthenware or porcelain. A plane surface is thus produced, in which the cavities of the stamped design appear as shadows of various depths, the parts in highest relief coming nearest the surface of the glaze, and thus having the effect of the lights of the picture. This process was introduced by the Baron A. De Trumblay of Itubelles, near Melun.

EMBALMING. (*Embaumement*, Fr.; *Einbalsmuen*, Germ.) An operation employed by the ancients to preserve human bodies from putrefaction. From their using *balans* in the process, the name was derived. See DISINFECTION, PUTREFACTION.

EMBOSSING. One of the plans introduced for **EMBOSSING CLOTH** by machinery which appears to be the most effective, is that of Mr. Thomas Greig, of Rose Bank, near Bury. This machine is thus constructed.

Figs. 717, 718 represent three distinct printing cylinders of copper, or other suitable material *a, n, c*, with their necessary appendages for printing three different colours upon the fabric as it passes through the machine; either of these cylinders *a, n, or c*, may be employed as an embossing cylinder, without performing the printing process, or may be made in effect both operations at the same time.

The fabric or goods to be operated upon being first wound tightly upon a roller, that roller is to be mounted upon an axle or pivot, bearing in arms or brackets at the back of the machine, as shown at *u*. From this roller the fabric *a a a* is conducted between tension rails, and passed under the bed cylinder or paper bowl *v*, and from thence proceeds over a carrier roller *x*, and over steam boxes not shown in the drawing, or it may be conducted into a hot room, for the purpose of drying the colours.

The cylinders *a, n, and c*, having either engraved or raised surfaces, are connected to feeding rollers *b, b, b*, revolving in the ink or coloured troughs *e, e, e*; or endless felts, called sieves, may be employed, as in ordinary printing machines, for supplying the colour, when the device on the surface of the cylinders is raised: these cylinders, may be furnished with doctors or scrapers when required, or the same may be applied to endless felts.

The blocks have adjustable screws *g, g*, for the purpose of bringing the cylinders up against the paper bowl with any required degree of pressure; the cylinder *a* is supported by gudgeons running in blocks, which blocks slide in the lower parts of the side frames, and are connected to perpendicular rods *f*, having adjustable, screw nuts.

The lower parts of these rods bear upon weighed levers *k, k*, extending in front of the machine; and by increasing the weights *l, l*, any degree of upward pressure may be given to the cylinder *a*.

The colour boxes or troughs *e, e, e*, carrying the feeding rollers *b, b, b*, are fixed on boards which slide in grooves in the side frames, and the rollers are adjusted and brought into contact with the surface of the printing cylinders by screws.

If a black cloth should be required to be introduced between the cylindrical bed or paper bowl *b*, and the fabric *a a a*, as the ordinary felt or blanket, it may, for printing, and embossing cotton, silk, or paper, be of linen or cotton; but if woollen goods are to be operated upon, a cap of felt, or some such material, must be bound round the paper bowl, and the felt or blanket must be used for the back cloth, which is to be conducted over the rollers *n* and *i*.

For the purpose of embossing the fabric, either of the rollers *a*, *n*, or *c*, may be employed, observing that the surface of the roller must be cut, so as to leave the pattern or device elevated for embossing velvets, plain cloths, and papers, but for woollens the device must be excavated, that is, cut in recess.

The pattern of the embossing cylinder will, by the operation, be partially marked through the fabric on to the surface of the paper bowl *b*; to obliterate which marks from the surface of the bowl, as it revolves, the iron cylinder roller *o* is employed; but as in the embossing of the same patterns on paper, a counter roller is required to produce the pattern perfectly, the iron roller is in that case dispensed with, the impression given to the paper bowl being required to be retained on its surface until the operation is finished.

In this case the relative circumferences of the embossing cylinder, and of the paper bowl, must be exactly proportioned to each other; that is, the circumference of the bowl must be equal, exactly, to a given number of circumferences of the embossing cylinder, very accurately measured in order to preserve a perfect register or synchronism, as they continue revolving between the pattern on the surface of the embossing cylinder and that indented into the surface of the paper bowl.

The axle of the paper bowl *a*, turns in brasses fitted into slots in the side frames, and it may be raised by hand from its bearings, when required, by a lever *h*, extending in front. This lever is affixed to the end of a horizontal shaft *t, t*, crossing the machine seen in the figures, at the back of which shaft there are two segment levers *p, p*, to which bent rods *q, q*, are attached, having hooks at their lower ends, passed under the axle of the bowl. At the reverse end of the shaft *t*, a ratchet-wheel *r*, is affixed, and a pull or click mounted on the side of the frame takes into the teeth of the wheel *r*, and thereby holds up the paper bowl when required.

When the iron roller *o*, is to be brought into operation, the vertical screws *f, f*, mounted in the upper parts of the side frames, are turned in order to bring down the brasses *x*, which carry the axle of that roller and slide in slots in the side frames.

The cylinders *a*, *n*, and *c*, are represented hollow, and may be kept at any desired temperature during the operation of printing, by introducing steam into them; and under the colour boxes *e, e, e*, hollow chambers are also made for the same purpose. The degree of temperature required to be given to these must depend upon the nature

of the colouring material, and of the goods operated upon. For the purpose of conducting steam to these hollow cylinders and colour boxes, pipes, as shown at *e, e, e*, are attached, which lead from a steam boiler. But when either of these cylinders is employed for embossing alone, or for embossing and printing at the same time, and particularly for some kinds of goods where a higher temperature may be required, a red-hot heater is then introduced into the hollow cylinder in place of steam.

If the cylinder *n*, is employed as the embossing cylinder, and it is not intended to print the fabric by that cylinder simultaneously with the operation of embossing, the feeding roller *b*, must be removed, and also the colour box *c*, belonging to that cylinder; and the cylinders *a* and *c* are to be employed for printing the fabric, the one applying the colour before the embossing is effected, the other after it. It is however to be remarked, that if *a* and *c* are to print colours on the fabric, and *n* to emboss it, in that case it is preferred, where the pattern would allow it. *a* and *c* are wooden rollers having the pattern upon their surfaces, and not metal, as the embossing cylinders must of necessity be.

It will be perceived that this machine will print one, two, or three colours at the same time, and that the operation of embossing may be performed simultaneously with the printing, by either of the cylinders *a*, *n*, or *c*, or the operation may be performed consecutively by the cylinders, either preceding or succeeding each other.

The situations of the doctors, when required to be used for removing any superfluous colour from the surface of the printing cylinder, are shown at *d, d, d*; those for removing any lint which may attach itself, at *e, e, e*. They are kept in their bearings by weighted levers and screws, and receive a slight lateral movement to and fro, by means of the vertical rod *m*, which is connected at top to an eccentric, on the end of the axle of the roller *n*, and at its lower end to a horizontal rod mounted at the side of the frame; to this horizontal rod, arms are attached, which are connected to the respective doctors; and thus by the rotation of the eccentric, the doctors are made to slide laterally.

When the cylinders *a*, *n*, or *c*, are employed for embossing only, these doctors will not be required. The driving power is communicated to the machine from any first mover through the agency of the toothed gear, which gives rotatory motion to the cylinder *n*, and from thence to the other cylinders *a*, and *c*, by toothed gear shown in fig. 717.

EMBOSSING LEATHER. Beautiful ornaments in basso-relievo for decorating the exteriors or interiors of buildings, models, cases, picture-frames, cabinet work, &c., have been recently made by the pressure of metallic blocks and dies by M. Claude Schroth. The dies are made of type metal, or of the fusible alloy with bismuth, called *d'Arceus*. The leather is beaten soft in water, then wrung, pressed, rolled, and felled as it were, by working it with the hands till it becomes thicker and quite supple. In this state it is laid on the mould, and forced into all its cavities by means of a wooden, bone, or copper tool. In other cases, the embossing is performed by the force of a press. The leather, when it has become dry, is easily taken off the mould, however deeply it may be inserted into its crevices by virtue of its elasticity.

EMBOSSING WOOD. (*Bossage*, Fr: *Erhabenheit, Arbeit*, Germ.) Raised figures upon wood, such as are employed in picture-frames, and other articles of ornamental cabinet work, are usually produced by means of carving, or by casting the pattern in plaster of Paris, or other composition, and cementing, or otherwise fixing it on the surface of the wood. The former mode is expensive; the latter is inapplicable on many occasions. The invention of Mr Streaker may be used either by itself, or in aid of carving, and depends on the fact, that if a depression be made by a blunt instrument on the surface of the wood, such depressed part will again rise to its original level by subsequent immersion in the water.

The wood to be ornamented having been first worked out in its proposed shape, is in a state to receive the drawing of the pattern; this being put on a blunt steel tool, or burnisher, or die, is to be applied successively to all those parts of the pattern intended to be in relief, and, at the same time, is to be driven very cautiously, without breaking the grain of the wood, till the depth of the depression is equal to the intended prominence of the figures. The ground is then to be reduced by planing or filing to the level of the depressed part; after which, the piece of wood being placed in water, either hot or cold, the part previously depressed will rise to its former height, and will then form an embossed pattern, which may be finished by the usual operations of carving. See CARVING BY MACHINE.

Another process which may be regarded either as carving or embossing wood, is that patented by Messrs. A. S. Braithwaite and Co.

Oak, mahogany, rose-wood, horse-chestnut, or other wood, is steeped in water for about two hours; and the cast iron mould containing the device is heated to redness, or sometimes to a white heat, and applied against the wood, either by a handle, as a branding iron, by a lever press, or by a screw-press, according to circumstances; the

moulds are made by the iron-founder from plaster casts of the original models or carvings.

Had not the wood been saturated with water, it would be ignited, but until the moisture is evaporated, it is only charred; it gives off volumes of smoke, but no flame. After a short time the iron is returned to the furnace to be re-heated, the blackened wood is well rubbed with a hard brush to remove the charcoal powder, which being a bad conductor of heat, saves the wood from material discoloration; and before the reapplication of the heated iron, the wood is again soaked in water, but for a shorter time, as it now absorbs moisture with more facility.

The rotation of burning, brushing, and wetting is repeated ten or twenty times, or upwards, until in fact the wood fills every cavity in the mould, the process being materially influenced by the character and condition of the wood itself, and the degrees to which heat and moisture are applied. The water so far checks the destruction of the wood, or even its change of any kind, that the burned surface, simply cleaned by brushing, is often employed, as it may be left either of a very pale or deep brown, according to the tone of colour required, so as to match old carvings of any age; or a very little scraping removes the discoloured surface. Perforated carvings are burned upon thick blocks of wood, and cut off with the circular saw.

EMBROIDERING MACHINE. (*Machine à broder*, Fr.; *Stechmaschine*, Germ.) This art has been from the earliest times a handicraft employment, cultivated on account of its elegance by ladies of rank. But M. Heilmann, of Mulhouse, invented a machine of a most ingenious kind, which enables a female to embroider any design with 80 or 140 needles as accurately and expeditiously as the formerly could do with one. A brief account of this remarkable invention will therefore be acceptable to many readers. It was first displayed at the national exposition of the products of industry in Paris for 1834. 130 needles were occupied in copying the same pattern with perfect regularity, all set in motion by one person.

Several of these machines are now mounted in France, Germany, and Switzerland, and, with some modifications, in Manchester, Glasgow, and Paisley.

The price of a machine having 130 needles, and of consequence 260 pincers or fingers and thumbs to lay hold of them, is 3000 francs, or 200*l.* sterling; and it is estimated to do daily the work of 15 expert hand embroiderers, employed upon the ordinary frame. It requires merely the labour of one grown-up person, and two assistant children. The operative must be well taught to use the machine, for he has many things to attend to: with the one hand he traces out, or rather follows the design with the point of the pantograph; with the other he turns a handle to plant and pull all the needles, which are seized by pincers and moved along by carriages, approaching to and receding from the web, rolling all the time along an iron railway; lastly, by means of two pedals, upon which he presses alternately with the one foot and the other, he opens the 130 pincers of the first carriage, which ought to give up the needles after planting them in the stuff, and he shuts with the same pressure the 130 pincers of the second carriage, which is to receive the needles, to draw them from the other side, and to bring them back again. The children have nothing else to do than to change the needles when all their threads are used, and to see that no needle misers its pincers.

This machine may be described under four heads: 1. the structure of the frame; 2. the disposition of the web; 3. the arrangement of the carriages; and 4. the construction of the pincers.

1. *The structure of the frame.*—It is composed of cast-iron, and is very massive. Fig. 719 exhibits a front elevation of it. The length of the machine depends upon the number of pincers to be worked. The model at the exposition had 260 pincers, and was 2 metres and a half (about 100 inches or 8 feet four inches English) long. The figure here given has been shortened considerably, but the other proportions are not disturbed. The breadth of the frame ought to be the same for every machine, whether it be long or short, for it is the breadth which determines the length of the thread to be put into the needles, and there is an advantage in giving it the full breadth of the model machine, fully 100 inches, so that the needles may carry a thread at least 40 inches long.

2. *Disposition of the piece to be embroidered.*—We have already stated that the pincers which hold the needles always present themselves opposite to the same point, and that in consequence they would continually pass backwards and forwards through the same hole, if the piece was not displaced with sufficient precision to bring successively opposite the tips of the needles every point upon which they are to work a design, such as a flower.

The piece is strained perpendicularly upon a large rectangular frame, whose four sides are visible in fig. 719; namely, the two vertical sides at *r r*, and the two horizontal sides, the upper and lower at *s s*. We see also in the figure two long wooden

rollers *o* and *o*, whose ends, mounted with iron studs, are supported upon the sides *r* of the frame, so as to turn freely. These form a system of beams upon which the piece

719

destined to receive the embroidery, is wound and kept vertically stretched to a proper degree, for each of these beams bears upon its end a small ratchet wheel *g, g*, the teeth of one of them being inclined in the opposite direction to those of the other. Besides the system of lower beams, there is another of two upper beams, which is however but imperfectly seen in the figure, on account of the interference of other parts in this view of the machine. One of these systems presents the web to the inferior needles, and the other to the upper needles. As the two beams are not in the same vertical plane, the plane of the web would be presented obliquely to the needles were it not for a straight bar of iron, round whose edge the cloth passes, and which renders it vertical. The piece is kept in tension crosswise by small brass templates, to which the strings *y'* are attached, and by which it is pulled towards the sides of the frame *r*. It remains to show by what ingenious means this frame may be shifted in every possible direction. M. Hailmann has employed for this purpose the pantograph which draughtsmen use for reducing or enlarging their plans in determinate proportions.

b b' f' b'' (fig. 719) represent a parallelogram, of which the four angles *b, b', f',*

b'' are jointed in such a way that they may become very acute or very obtuse at pleasure, while the sides of course continue of the same length; the sides $b' b''$ and $b b'$ are parallelograms, the one to the point d , and the other to the point e , and these points e and d are chosen under the condition that in one of the positions of the parallelogram, the line $c d$ which joins them passes through the point f ; this condition may be fulfilled in an infinite number of manners, since the position of the parallelogram remaining the same, we see that if we wished to shift the point d further from the point b' , it would be sufficient to bring the point e near enough to b'' , or vice versa; but when we have once fixed upon the distance $b' d$, it is evident that the distance $b'' e$ is its necessary consequence. Now the principle upon which the construction of the pantograph rests is this; it is sufficient that the three points d, f , and e be in a straight line, in one only of the positions of the parallelogram, in order that they shall remain always in a straight line in every position which can possibly be given to it.

We see in the figure that the side $b c$ has a handle n'' with which the workman puts the machine in action. To obtain more precision and solidity in work, the sides of the pantograph are jointed, so that the middle of their thickness lies exactly in the vertical plane of the piece of goods, and that the axes of the joints are truly perpendicular to this plane, in which consequently all the displacements are effected. We arrive at this result by making fast to the superior great cross bar v'' an elbow piece d'' , having a suitable projection, and to which is adapted in its turn the piece d' , which receives in a socket the extremity of the side $b d$; this piece d' is made fast to d'' by a bolt, but it carries an oblong hole, and before screwing up the nut, we make the piece advance or recede, till the fulcrum point comes exactly into the plane of the web. This condition being fulfilled, we have merely to attach the frame to the angle f of the parallelogram, which is done by means of the piece r'' .

It is now obvious that if the embroiderer takes the handle n'' in his hand and makes the pantograph move in any direction whatever, the point f will describe a figure similar to the figure described by the point e , and six times smaller, but the point f cannot move without the frame, and whatever is upon it moving also. Thus in the movement of the pantograph, every point of the web describes a figure equal to that described by the point f , and consequently similar to that described by the point e , but six times smaller; the embroidered object being produced upon the cloth in the position of that of the pattern. It is sufficient therefore to give the embroidering operative who holds the handle n'' a design six times greater than that to be executed by the machine, and to afford him at the same time a sure and easy means of tracing over with the point e , all the outlines of the pattern. For this purpose he adapts to e , perpendicularly to the plane of the parallelogram, a small style terminated by a point e'' , and he fixes the pattern upon a vertical tablet x , parallel to the plane of the stuff and the parallelogram, and distant from it only by the length of the style e'' ; this tablet is carried by the iron rod e' , which is secured to a cast iron foot x' , serving also for other purposes, as we shall presently see. The frame loaded with its beams and its cloth forms a pretty heavy mass, and as it must not swerve from its plane, it needs to be lightened, in order that the operative may cause the point of the pantograph to pass along the tablet without straining or uncertainty in its movements. M. Heilmann has accomplished these objects in the following way. A cord c attached to the side $b e$ of the pantograph passes over a return pulley, and carries at its extremity a weight which may be graduated at pleasure; this weight equipoises the pantograph, and tends slightly to raise the frame. The lower side of the frame carries two rods u and u' , each attached by two arms h, h' , a little bent to the left; both of these are engaged in the grooves of a pulley. Through this mechanism a pressure can be exercised upon the frame from below upwards which may be regulated at pleasure, and without preventing the frame from moving in all directions, it hinders it from deviating from the primitive plane to which the pantograph was adjusted. The length of the rods u ought to be equal to the amount of the lateral movement of the frame. Two guides v, v' , carried by two legs of cast iron, present vertical slots in which the lower part of the frame v' is engaged.

3. *Disposition of the carriages.*—The two carriages, which are similar, are placed the one to the right, and the other to the left of the frame. The carriage itself is composed merely of a long hollow cylinder of cast iron L , carrying at either end a system of two grooved castors or pulleys z , which roll upon the horizontal rails k ; the pulleys are mounted upon a forked piece l , with two ends to receive the axes of the pulleys, and the piece l is itself bolted to a projecting ear l' cast upon the cylinder.

This assemblage constitutes, properly speaking, the carriage, resting in a perfectly stable equilibrium upon the rails k , upon which it may be most easily moved backwards and forwards, carrying its train of needles to be passed or drawn through the cloth.

M. Heilmann has contrived a mechanism by which the operative, without touching

from his place, may conduct the carriages, and regulate as he pleases the extent of their course, as well as the rapidity of their movements. By turning the axes m'' in the one direction or the other, the carriage may be made to approach to, or recede from, the web.

When one of the carriages has advanced to prick the needles into the stuff, the other is there to receive them; it lays hold of them with its pincers, pulls them through, performs its course by withdrawing to stretch the thread, and close the stitch, then it goes back with the needles to make its pricks in return. During these movements, the first carriage remains at its post waiting the return of the second. Thus the two carriages make in succession an advance and a return, but they never move together.

To effect these movements M. Heilmann has attached to the piece o' made fast to the two uprights a and b of the frame, a bent lever n o m' m'' , movable round the point o ; the bend n carries a toothed wheel o' , and the extremity m'' a toothed wheel o'' ; the four wheels m , m' , o' , and o'' , have the same number of teeth and the same diameter; the two wheels o' and o'' are fixed in reference to each other, so that it is sufficient to turn the handle n to make the wheel o' revolve, and consequently the wheel o'' ; when the lever n o is vertical, the wheel o' touches neither the wheel m nor the wheel m' ; but if it be inclined to the one side or the other, it brings the wheel o' alternately into gear with the wheel m or the wheel m' . As the operative has his two hands occupied, the one with the pantograph, and the other with the handle of impulsion, he has merely his feet for acting upon the lever n o , and as he has many other things to do, M. Heilmann has adapted before him a system of two pedals, by which he executes with his feet a series of operations no less delicate than those which he executes with his hands.

The pedals r are movable round the axis p , and carry cords p' wound in an opposite direction upon the pulleys r ; these pulleys are fixed upon a movable shaft r'' supported upon one side by the prop m' , and on the other in a piece k' attached to the two great uprights of the frame. In depressing the pedal r (now raised in the figure), the upper part of the shaft r'' will turn from the left to the right, and the lever n o will become inclined so as to carry the wheel o' upon the wheel m' , but at the same time the pedal which is now depressed will be raised, because its cord will be forced to wind itself upon its pulley, as much as the other cord has unwound itself; and thus the apparatus will be ready to act in the opposite direction when wanted.

4. *Disposition of the pincers*. — The shaft l' carries, at regular intervals of a semi-diameter, the appendages q q cast upon it, upon which are fixed, by two bolts, the curved branches q destined to bear the whole mechanism of the pincers. When the pincers are opened by their appropriate leverage, and the half of the needle, which is pointed at each end, with the eye in the middle, enters the opening of its plate, it gets lodged in an angular groove, which is less deep than the needle is thick, so that when the pincers are closed, the upper jaw presses it into the groove. In this way the needle is firmly held, although touched in only three points of its circumference.

Suppose now, that all the pincers are mounted and adjusted at their proper distances upon their prismatic bar, forming the upper range of the right carriage. For opening all the pincers there is a long plate of iron, u , capable of turning upon its axis, and which extends from the one end of the carriage to the other. This axis is carried by a kind of forks which are bolted to the extremity of the branches q . By turning that axis the workman can open the pincers at pleasure, and they are again closed by springs. This movement is performed by his feet acting upon the pedals.

The threads get stretched in proportion as the carriage is run out, but as this tension has no elastic play, inconveniences might ensue, which are prevented by adapting to the carriage a mechanism by means of which all the threads are pressed at the same time by a weight susceptible of graduation. A little beneath the prismatic bar, which carries the pincers, we see in the figure a shaft v , going from one end of the carriage to the other, and even a little beyond it; this shaft is carried by pieces y which are fixed to the arms q , and in which it can turn. At its left end it carries two small bars y' and y'' , and at its right a single bar y' , and a counterweight (not visible in this view); the ends of the two bars y' are joined by an iron wire, somewhat stout and perfectly straight. When the carriage approaches the web, and before the iron wire can touch it, the little bar w presses against a pin w' , which rests upon it, and tends to raise it more and more. In what has preceded we have kept in view only the upper range of pincers and needles, but there is an inferior range quite similar, as the figure shows, at the lower ends of the arms q . In conclusion, it should be stated, that the operative does not follow slidingly with the pantograph the trace of the design which is upon the tablet or the picture, but he must stop the point of the style upon the point of the pattern into which the needle should enter, then remove it, and put it down again upon the point by which the needle ought to re-enter in coming from the other side of the piece, and so on in succession. To facilitate this kind of reading off, the pattern upon the tablet is composed of right lines terminated by the points for the entrance and

return of the needle, so that the operative (usually a child) has continually under her eyes the series of broken lines which must be followed by the pantograph. If she happens to quit this path an instant, without having left a mark of the point at which she had arrived, she is under the necessity of looking at the piece to see what has been already embroidered, and to find by this comparison the point at which she must resume her work, so as not to leave a blank, or to repeat the same stitch.

Explanation of Figure.

- A, lower cross bars, which unite the legs of the two ends of the frame.
 a, the six feet of the front end of the frame.
 a', the six feet of the posterior end of the frame.
 a'', curved pieces which unite the cross bars A'' to the uprights.
 a''', handle of the pantograph.
 b, b', b'', three angles of the pantograph.
 c, point of the side b b'' on which the point is fixed.
 c'', point of the pantograph.
 d, cross bar in form of a gutter, which unites the upper parts of the frame.
 d', fixed point, round which the pantograph turns.
 e, tablet upon which the pattern to be embroidered is put.
 e', support of that tablet.
 e, cord attached at one end to the side b c of the pantograph passing over a guide pulley, and carrying a weight at the other end.
 e'', iron rod by which the tablet e is joined to its support e'.
 f, f, uprights of the cloth-carrying frame.
 f', f', horizontal sides of the same frame.
 g, four roll beams.
 g'', the piece of cloth.
 g', the strings, which serve to stretch the cloth laterally.

This machine has not been applied for embroidering nets or muslins, as these fabrics are not sufficiently close to hold the needles; it has been hitherto used for embroidering cloth for vests and other purposes, and silk for ladies' dresses. We learn, however, that some very satisfactory experiments have been made by the Messrs. Houldsworth of Manchester, which promise shortly to lead to the successful application of these machines to the finer description of fabrics.

EMERY. This mineral was long regarded as an ore of iron; and was called by Pliny *ferreus quartziferus*. It is, however, a massive granular or compact variety of corundum, more or less impure. It is very abundant in the island of Naxos, at Cape Emery, whence its name. From this place it is imported in large quantities. It occurs also in the islands of Jersey and Guernsey, at Almaden in Poland, Saxony, Sweden, Persia, &c. Its colour varies from red brown to dark brown; its specific gravity is about 4000; it is so hard as to scratch quartz and many precious stones.

We have recent accounts of emery discoveries in Minnesota, but nearly all that is used at present in the arts comes from Turkey, near ancient Smyrna. Dr. Lawrence Smith, the American geologist, made a discovery of a deposit of emery while reading in Smyrna, and he made an examination of the locality in 1817. Dr. Smith having reported his discoveries to the Turkish government, a commission of inquiry was instituted, and the business soon assumed a mercantile form. The monopoly of the emery of Turkey was sold to a mercantile house in Smyrna, and since then the price has diminished in the market.

The following analyses are quoted by Dana from an elaborate paper by J. Lawrence Smith, in the *American Journal of Science*.

	Hardness, sapphire being 10.	Specific Gravity.	Alumina.	Oxide of Iron.	Lime.	Silica.	Water.

The mining of the emery is of the simplest character. The natural decomposition of the rock in which it occurs facilitates its extraction. The rock decomposes in an

such, in which the emery is found in bold lumps. The quantities procured under these circumstances is so great that it is rarely a necessity to explore the rock. The earth in the neighbourhood of the block is almost always of a red colour, and serves as an indication to those who are in search of the mineral. Sometimes, before beginning to excavate, the spots are sounded by an iron rod with a steel point, and when any resistance is met with, the rod is rubbed in contact with the resisting body, and the effect produced on the point enables a practised eye to decide whether it has been done by emery or not. The blocks which are of a convenient size are transported in their natural state, but they are frequently broken by large hammers; when they resist the action of the hammer, they are subjected to the action of fire for several hours, and on cooling they most commonly yield to blows. It sometimes happens that large masses are abandoned, from the impossibility of breaking them into pieces of a convenient size, as the transportation, either on canals or horses, requires that the pieces shall not exceed 100 lbs each in weight.

When reduced to a powder, emery varies in colour from dark grey to black. The colour of its powder affords no indication of its commercial value. The powder examined under the microscope shows the distinct existence of two minerals, corundum and oxide of iron. Emery, when moistened, always affords a very strong argillaceous colour. Its hardness is its most important property in its application to the arts, and was ascertained by Mr. Smith in the following manner:—Fragments were broken from the piece to be examined, and crushed in a diamond mortar with two or three blows of a hammer, then thrown into a sieve with 400 holes to the inch. The powder is then weighed, and the hardness tested with a circular piece of glass, about four inches in diameter, and a small agate mortar. The glass is first weighed, and placed on a piece of glazed paper; the pulverised emery is then thrown upon it at intervals, rubbing it against the glass with the bottom of the agate mortar. The emery is brushed off the glass from time to time with a feather, and when all the emery has been made to pass once over the glass, it is collected, and passed through the same operation three or four times. The glass is then weighed, again subjected to the same operation, the emery by this time being reduced to an impalpable powder. This series of operations is continued until the loss sustained by the glass is exceedingly small. The total loss in the glass is then noted, and when all the specimens of emery are submitted to this operation under the same circumstances, an exact idea of their relative hardness is obtained. The advantages of using glass and agate are, that the latter is sufficiently hard to crush the emery, and in a certain space of time to reduce it to such an impalpable state, that it has no longer any sensible effect on the glass; and, on the other hand, the glass is soft enough to lose during this time sufficient of its substance to allow of accurate comparative results. By this method, the best emery was found capable of wearing away about half of its weight of common French window-glass.

In the ordinary process, the lumps of emery are broken up in the same manner as stone is for repairing macadamised roads, and into lumps of similar size. These lumps are then crushed under stampers, such as are used for pounding metalliferous ores, driven by water or by steam power. It is supposed that the stampers leave the fragments more angular than they would be if they were ground under runners, a mode which is sometimes employed. The coarse powder is then sifted through sieves of wire cloth, which are generally cylindrical, like the bolting cylinders of corn-mills; but the sieves are covered with wire cloth, which vary from ninety to sixteen wires to the inch. No. 16 sieve gives emery of about the size of mustard seed; and coarser fragments, extending nearly to the size of pepper-corns, are also occasionally prepared for the use of engineers. The sieves have sometimes as many as 120 wires to the inch; but the very fine sizes of emery are most commonly sifted through lawn sieves. The finest emery that is obtained from the manufacturers is that which floats in the atmosphere of the stamping-room, and is deposited on the beams and shelves, from which it is occasionally collected. The manufacturers rarely or never wash the emery; this is mostly done by the glass-workers, and such others as require a greater degree of precision than can be obtained by sifting.

The following table shows the number of wires usually contained in the sieves, and the names of the kinds respectively produced by them:—

Wires.		Wires.	
Corn emery - - -	16	Coarse flour emery - - -	60
Coarse grinding emery - -	24	Flour emery - - -	70
Grinding emery - - -	36	Fine flour emery - - -	80
Fine grinding emery - - -	46	Superfine flour emery - -	90
Superfine grinding emery -	53		

Washing emery by hand is far too tedious for those who require very large quantities of emery, such as the manufacturers of plate glass and some others, who generally adopt the following method.—Twelve or more cylinders of sheet copper, of the common height of about two feet, and varying from about three, five, eight, to thirty or forty inches in diameter, are placed exactly level, and communicating at their upper edges, each to the next, by small troughs or channels; the largest vessel has also a waste-pipe near the top. At the commencement of the process, the cylinders are all filled to the brim with clean water; the pulverised emery is then churned up with abundance of water in another vessel, and allowed to run into the smallest or the three-inch cylinder, through a tube opposite the gutter leading to the second cylinder. The water during its short passage across the three-inch cylinder, deposits in that vessel such of the coarsest emery as will not bear suspension for that limited time; the particles next finer are deposited in the five-inch cylinder, during the somewhat longer time the mixed stream takes in passing the brim of that vessel; and so on. Eventually the water forms a very languid eddy in the largest cylinder, and deposits therein the very fine particles that have remained in suspension until this period; and the water, lastly, escapes by the waste-pipe nearly or entirely free from emery. In this simple arrangement, time is also the measure of the particles respectively deposited in the manufacture to which the emery is applied. When the vessels are to a certain degree filled with emery, the process is stopped, the vessels are emptied, the emery is carefully dried and laid by, and the process is recommenced.

Holtzapffel informs us that he has been in the habit, for many years, of employing emery of twelve degrees of fineness, prepared by him, if by washing over.

For optical purposes, Mr. Ross mixes four pounds of the flour of emery of coarseness, with one ounce of powdered gum-arabic, and then throws the powder into two gallons of clear water; and he collects the deposit at the end of 10', and 30', and 2 10' 20' and 60', and that which is not deposited by one hour's subsidence is thrown away as useless for grinding lenses.

Emery paper is prepared by brushing the paper over with thin glue, and dusting the emery-powder over it from a sieve. There are about six degrees of coarseness. Sieves with thirty and ninety meshes per linear inch, are in general the coarsest and finest sizes employed. When used by artisans, the emery-paper is commonly wrapped round a fin or a slip of wood, and applied just like a file, with or without oil, according to circumstances. The emery-paper cuts more smoothly with oil, but leaves the work dull.

Emery cloth only differs from emery-paper in the use of thin cotton cloth instead of paper, as the material upon which the emery is fixed by means of glue. The emery cloth, when folded around a file, does not fly so readily to it as emery-paper, and is apt to enroll. Hence smiths, engineers, and others, prefer emery-paper and emery-sticks; but for household and other purposes, where the hand alone is used, the greater durability of the cloth is advantageous.

Emery-sticks are rods of board about eight or twelve inches long, planed up square, or with one side rounded like a half round file. Nails are driven to each end of the stick as temporary handles; they are then brushed over one at a time with thin glue, and dabbed at all parts in a heap of emery powder, and knocked on one end to shake off the excess. Two coats of glue and emery are generally used. The emery-sticks are much more economical than emery-paper wrapped on a file, which is liable to be torn.

Emery-cake consists of emery mixed with a little beeswax, so as to constitute a solid lump, with which to dress the edges of buff and glass wheels. The ingredients should be thoroughly incorporated by stirring the mixture while fluid, after which it is frequently poured into water, and thoroughly kneaded with the hands, and rolled into lumps before it has time to cool. The emery-cake is sometimes applied to the wheels whilst they are revolving; but the more usual course is, to stop the wheel and rub in the emery cake by hand. It is afterwards smoothed down by the thumb.

Emery-paper, or patent razor-strop paper, an article in which fine emery and glass are mixed with paper pulp, and made into sheets as in making ordinary paper; the emery and glass are said to constitute together 60 per cent. of the weight of the paper, which resembles drawing-paper, except that it has a delicate fawn colour. The emery-paper is directed to be pasted or glued upon a piece of wood, and when rubbed with a little oil, to be used as a razor-strop.

In 1842, Mr. Henry Barclay took out a patent for a method of combining powdered emery into discs and lumps of different kinds, suitable to grinding, cutting, and polishing glass, metals, and other hard substances. The process of manufacture is as follows:—Coarse emery-powder is mixed with about half its weight of pulverised Stourbridge loam, and a little water or other liquid, to make a

thick paste; this is pressed into a metallic mould by means of a screw-press, and after having been thoroughly dried, is baked or burned in a muffle or close receiver at a temperature considerably above a red heat and below the full white heat. In this case, the clay or alumina serves as a bond, and unites the particles very completely into a solid artificial emery-stone, which cuts very greedily, and yet seems hardly to suffer perceptible wear.

Superfine grinding emery is formed into wheels exactly in the same manner as the above, but the proportion of loam is then only one-fourth instead of one-half that of the emery. These emery stones, which are of medium fineness, cut less quickly, but more smoothly than the above.

Flour-emery, when manufactured into artificial stones, requires no anitig substance, but the moistened powder is forced into the metal mould and fired; some portions of the alumina being sufficient to unite the whole. These fine wheels render the works submitted to them exceedingly smooth, but they do not produce a high polish on account of the comparative coarseness of the flour-emery.

The alumina of emery is believed to be aggregated to the same degree of hardness as in corundum or almandine spar; which is one of the hardest minerals known. Emery is extensively employed for grinding metals, glass, &c; for which purpose it is reduced to powders of different degrees of fineness by grinding and elutriation.

EMERALD (*Emeraude*, Fr.; *Smaragd*, Germ.), is a precious stone of a beautiful green colour; valued next to diamond, and in the same rank as oriental ruby and sapphire. It occurs in prisms with a regular hexagonal base; sp. grav. 2.7; scratches quartz with difficulty; is scratched by topaz; fusible at the blowpipe into a frothy bead; the precipitate afforded by ammonia, from its solution, is soluble, in a great measure, in carbonate of ammonia. Its analysis is given very variously by different chemists. It contains about 14 per cent. of glucina, which is its characteristic constituent, along with 68 of silica, 16 of alumina, a very little lime and iron. The beautiful emerald of Peru is found in a clay schist mixed with some calcareous matter. A stone of 4 grains weight is said to be worth from 4*l.* to 5*l.*; one of 4 grains, 10*l.*; one of 15 grains, being fine, is worth 60*l.*; one of 24 grains fetched, at the sale of M. de Bré's cabinet, 2400 francs, or nearly 100*l.*

The beryl is analogous in composition to the emerald, and is employed (when of the common opaque kind, found near Lunoges) by chemists for procuring the earth glucina.

True emeralds are found in a vein of dolomite, which traverses the hornblende slate at Muzo, north of Santa Fé de Bogotá. A perfect hexagonal crystal from this locality, two inches long, is in the cabinet of the Duke of Devonshire; it measures across its three diameters 2½ in., 2½ in., 1½ in., and weighs 8 oz. 19 dwts.—owing to flaws, it is but partially fit for jewellery. A more splendid specimen, though somewhat smaller, weighing but 6 oz., is in the possession of Mr. Hope; it cost 500*l.* Emeralds of less beauty, but much larger, occur in Siberia. One specimen in the royal collection measures 1½ inches long and 12 broad, and weighs 16½ lbs. troy; another is 7 inches long and 4 inches broad, and weighs 6 lbs. troy.—*Dana.*

The emerald is generally believed to derive its colour from the presence of a minute quantity of oxide of chrome, the beryl from oxide of iron.

This mineral has been recently examined with great care by M. Lewy, from whose communication to the Academy of Sciences we abstract the following:

"M. Lewy visited a mine called Muzo, in New Granada, Mexico, and obtained some fine specimens of emeralds, and of the rocks in which these precious stones are found. He observed that the largest and finest emeralds could be reduced to powder by a slight squeezing or rubbing between the fingers when first obtained, but that they acquired hardness after a certain time and repose. It has been commonly stated that the colouring matter of the emerald is chrome, but M. Lewy attributes it to an organic colouring matter, analogous to *chlorophyll*. He states that the emerald exposed to heat loses all colour; whereas minerals coloured by chrome, do not lose their green colour by ignition. His analysis of the Mexican mineral is as follows:—

Silica	-	-	-	-	-	67.9
Alumina	-	-	-	-	-	17.9
Glucina	-	-	-	-	-	12.4
Magnesia	-	-	-	-	-	0.9
Soda	-	-	-	-	-	0.7

The green colour of the emerald is darkest in those specimens which furnish to analysis most organic matter: it is completely destroyed by heat, becoming white and opaque.

EMETINE. A base constituting the emetic principle in ipecacuanha.—C. G. W.

EMPYREUMA, means the offensive smell produced by fire applied to organic matters, chiefly vegetable, in close vessels. Thus, empyreumatic vinegar is obtained by distilling wood at a red heat, and empyreumatic oil from many animal substances in the same way.

ENAMELS (*Émaux*, Fr.; *Schmelzglas*, Germ.) are varieties of glass, generally opaque or coloured, always formed by the combination of different metallic oxides, to which certain fixed fusible salts are added, such as the borates, fluxes, and phosphates.

The simplest enamel, and the one which serves as a basis to most of the others, is obtained by calcining first of all a mixture of lead and tin, in proportions varying from 15 to 50 parts of tin for 100 of lead. The middle term appears to be the most suitable for the greater number of enamels; and this alloy has such an affinity for oxygen, that it may be calcined with the greatest ease in a flat cast-iron pot, and at a temperature not above a cherry red, provided the dose of tin is not too great. The oxide is drawn off in the sides of the melted metal, according as it is generated, new pieces of the alloy being thrown in from time to time, till enough of the powder be obtained. Great care ought to be taken that no metallic particles be left in the oxide, and that the calcining heat be as low as is barely sufficient; for a strong fire frits the powder, and obstructs its subsequent comminution. The powder when cold is ground in a proper mill, levigated with water, and elutriated. In this state of fineness and purity, it is called *calceine* or flux, and it is mixed with silicious sand and some alkaline matter or sea-salt. The most ordinary proportions are, 4 of sand, 1 of sea-salt, and 4 of calceine. Chaptal states, that he has obtained a very fine product from 100 parts of calcine, made by calcining equal parts of lead and tin, 100 parts of ground flint, and 200 parts of pure sub-carbonate of potash. In either case, the mixture is put into a crucible, or laid simply on a stratum of sand, quicklime spontaneously slacked, or wood-ashes, placed under a pottery or porcelain kiln. This mass undergoes a semivitrification, or even a complete fusion on its surface. It is this kind of frit which serves as a radical in almost every enamel; and by varying the proportions of the ingredient, more fusible, more opaque, or whiter enamels are obtained. The first of these qualities depends on the quantity of sand or flux, and the other two on that of the tin.

The sea-salt employed as a flux may be replaced either by salt of tartar, by pure potash, or by soda; but each of these fluxes gives peculiar qualities to the enamel.

Most authors who have written on the preparation of enamels, insist a great deal on the necessity of selecting carefully the particular sand that should enter into the composition of the frit, and they even affirm that the purest is not the most suitable. Chaptal states, in the 34th volume of the *Annales de Chimie*, that the sand ought to contain at least 1 part of tale for 5 of silicious matter, otherwise the enamel obtained is never very glassy, and that some wrinkled spots from imperfect fusion are seen on its surface; and yet we find it prescribed in some old treatises, to make use of ground flints, fritted by means of salt of tartar or some other flux. It would thence appear that the presence of tale is of no use towards the fusibility of the silica, and that its absence may be supplied by increasing the dose of the flux. In all cases, however, we ought to beware of metallic oxides in the sand, particularly those of iron and manganese, which most frequently occur, and always injure the whiteness of the frit.

The ancients carried the art of enamelling to a very high perfection, and we occasionally find beautiful specimens of their work. Then, as at present, each artist made a mystery of the means that succeeded best with him, and thus a multitude of envious processes have been buried with their authors.

The Venetians are still in possession of the best enamel processes, and they supply the French and other nations with the best kinds of enamel, of every coloured shade.

Enamels are distinguished into transparent and opaque; in the former all the elements have experienced an equal degree of liquefaction, and are thus run into crystal glass, whilst in the others, some of their elements have resisted the action of heat, so that their particles prevent the transmission of light. This effect is produced particularly by the oxide of tin.

The frits for enamels that are to be applied to metallic surfaces require greater fusibility, and should therefore contain more flux; and the sand used for these should be calcined beforehand with one-fourth its weight of sea-salt; sometimes, indeed, metallic fluxes are added, as minium or litharge. For some metallic colours, the oxides of lead are very injurious, and in this case recourse must be had to other fluxes. Chaptal states that he has derived advantage from the following mixtures, as bases for purples, blues, and some other delicate colours:—

Three parts of silicious sand, one of chalk, and three of calcined borax; or, three of glass (of broken crystal goldets), one of calcined borax, one-fourth of a part of nitre.

and one part of well-washed diaphoretic antimony. These compositions afford a very white enamel, which accords perfectly well with blue.

It is obvious that the composition of this primary matter may be greatly varied; but we should never lose sight of the essential quality of a good enamel; which is, to acquire, at a moderate heat, sufficient fluidity to take a shining surface, without running too thin. It is not complete fusion which is wanted; but a pasty state, of such a degree as may give it, after cooling, the aspect of having suffered complete liquefaction.

Dead-white Enamel.—This requires greater nicety in the choice of its materials than any other enamel, as it must be free from every species of tint, and be perfectly white; hence the frit employed in this case should be itself composed of perfectly pure ingredients. But a frit should not be rejected hastily because it may be somewhat discoloured, since this may depend on two causes; either on some metallic oxide, or on fuliginous particles proceeding from vegetable or animal substances. Now the latter impurities may be easily removed by means of a small quantity of permanganate of manganese, which has the property of readily parting with a portion of its oxygen, and of thus fuel-tinting the combustion, that is to say, the destruction of the colouring carbonaceous matter. Manganese indeed possesses a colouring power itself on glass, but only in its highest state of oxidation, and when reduced to the lower state, as is done by combustible matters, it no longer communicates colour to the enamel combinations. Hence the proportion of manganese should never be in excess; for the surplus would cause colour. Sometimes, indeed, it becomes necessary to give a little manganese-colour, (i.e. a pink tint) in order to obtain a more agreeable shade of white; as a little azure blue is added to linens, to brighten or counteract the dulness of their yellow tints.

A white enamel may be conveniently prepared also with a calcine composed of two parts of tin and one of lead calcined together; of this combined oxide, one part is melted with two parts of fine crystal and a very little manganese, all previously ground together. When the fusion is complete, the vitreous matter is to be poured into clear water, and the frit is then dried, and melted anew. The pouring into water and fusion are sometimes repeated four times, in order to secure a very uniform combination. The crumble must be carefully screened from smoke and flame. The smallest portions of oxide of iron or copper admitted into this enamel will destroy its value.

Some practitioners recommend the use of washed diaphoretic antimony (antimoniate of potash, from metallic antimony, and nitre deflagrated together) for white enamel; but this product cannot be added to any preparation of lead or other metallic oxides; for it would tend rather to tarnish the colour than to clear it up; and it can be used therefore only with ordinary glass, or with saline fluxes. For three parts of white glass (without lead) one part of washed diaphoretic antimony is to be taken; the substances are well ground together, and fused in the common way.

Blue Enamel.—This fine colour is almost always obtained from the oxide of cobalt or some of its combinations, and it produces it with such intensity that only a very little can be used, lest the shade should pass into black. The cobalt blue is so rich and lively that it predominates in some measure over every other colour, and masks many so that they can hardly be perceived; it is also most easily obtained. To bring it out, however, in all its beauty, the other colours must be removed as much as possible, and the cobalt itself should be tolerably pure. This metal is associated in the best known ores with a considerable number of foreign substances—arsenic, copper, nickel, and sulphur, and it is difficult to separate them completely; but for enamel blues, the oxide of cobalt does not require to be perfectly free from all foreign metals; the iron, nickel, and copper being most prejudicial, should be carefully eliminated. This object may be most easily attained by dissolving the ore in nitric acid, evaporating the solution to a syrupy consistence, to expel the excess of acid, and separate a portion of arsenic. It is now diluted with water, and solution of carbonate of soda is dropped slowly into it with brisk agitation, till the precipitate, which is at first of a whitish gray, begins to turn of a rose-red. Whenever this colour appears, the whole must be thrown on a filter, and the liquid which passes through must be treated with more of the carbonate of soda, in order to obtain the arseniate of cobalt, which is nearly pure. Since arsenic acid and its derivatives are not capable of communicating colour themselves, and as they moreover are volatile, they cannot impair the beauty of the blue, and hence this preparation affords it in great perfection.

Metallic fluxes are not the most suitable for this colour; because they always communicate a tint of greater or less force, which never fails to injure the purity of the blue. Nitre is a useful addition, as it keeps the oxide at the maximum of oxidation, in which state it produces the richest colour.

Yellow Enamel.—There are many processes for making this colour in enamel; but it is somewhat difficult to fix, and it is rarely obtained of an uniform and fine tint. It may be produced directly with some preparations of silver, as the phosphate or sulphate; but this method does not always succeed, for too strong a heat or powerful fluxes readily destroy it, and silver is particularly prejudicial. This uncertainty of success with the salts of silver causes them to be seldom employed; and oxides of lead and antimony are therefore preferred, which afford a fine yellow when combined with some oxides that are refractory enough to prevent their complete vitrification. One part of white oxide of antimony may be taken with from one to three parts of white lead, one of alum, and one of sal-ammoniac. Each of these substances is to be pulverised, and then all are to be exactly mixed, and exposed to a heat adequate to decompose the sal-ammoniac. This operation is judged to be finished when the yellow colour is well brought out. There is produced here a combination quite analogous to that known under the name of Naples yellow.

Other shades of yellow may be procured either with the oxide of lead alone, or by adding to it a little red oxide of iron; the tints varying with the proportion of the latter.

Clouet says, in his Memoir on Enamels, that a fine yellow is obtained with pure oxide of silver, and that it is merely necessary to spread a thin coat of it on the spot to be coloured. The piece is then exposed to a moderate heat, and withdrawn as soon as this has reached the proper point. The thin film of metallic silver revived on the surface being removed, the place under it will be found tinged with a fine yellow, of hardly any thickness. As the pellicle of silver has to be removed which covers the colour, it is requisite to avoid fixing this film with fluxes; and it ought therefore to be applied after the fusion of the rest. The yellows require in general but little alkaline flux, as they answer better with one of a metallic nature.

Green Enamel.—It is known that a green colour may be produced by a mixture of yellow and blue; but recourse is seldom had to this practice for enamels, as they can be obtained almost always directly with the oxide of copper; or, still better, with the oxide of chrome, which has the advantage of resisting a strong heat.

Chemists describe two oxides of copper, the protoxide of an orange colour, which communicates its colour to enamels, but it is difficult to fix; the deutoxide is blue in the state of hydrate, but blackish-brown when dry, and it colours green all the vitreous combinations into which it enters. This oxide requires, at most one or two proportions of flux, either saline or metallic, to enter into complete fusion; but a much smaller dose is commonly taken, and a little oxide of iron is introduced. To 4 pounds of flux, for instance 2 ounces of oxide of copper and 45 grains of red oxide of iron are used; and the ordinary measures are pursued for making very homogeneous enamel.

The green produced by oxide of chrome is much more solid; it is not altered by a powerful fire, but it is not always of a fine shade. It generally inclines too much to the dead-leaf yellow, which depends on the degree of oxygenation of the chrome.

Red Enamel.—We have just stated, that protoxide of copper affords a fine colour when it could be fixed, a result difficult to obtain on account of the fugitive nature of this oxide; slight variations of temperature enabling it to absorb more oxygen. The proper point of fusion must be seized for taking it from the fire whenever the desired colour is brought out. Indeed, when a high temperature has produced peroxidisation, this may be corrected by adding some combustible matter, as charcoal, tallow, tartar, &c. The copper then returns to its minimum of oxidation, and the red colour which had vanished, reappears. It is possible, in this way, and by pushing the heat a little, to accomplish the complete reduction of a part of the oxide; and the particles of metallic copper thereby disseminated in a reddish ground, give this enamel the aspect of the stone called *aventurin*. The surest and easiest method of procuring protoxide of copper is to boil a solution of equal parts of sugar, and sulphate or rather acetate of copper, in four parts of water. The sugar takes possession of a portion of the oxygen of the cupreous oxide, and reduces it to protoxide; when it may be precipitated in the form of a granular powder of a brilliant red. After about two hours moderate ebullition, the liquid is set aside to settle, decanted off the precipitate, which is washed and dried.

The protoxide properly employed by itself, furnishes a red which vies with the finest carmine, and by its means every tint may be obtained from red to orange, by adding a greater or smaller quantity of peroxide of iron.

The preparations of gold, and particularly the oxide and purple of Cassius, are likewise employed with advantage to colour enamel red, and this composition resists a powerful fire tolerably well. For some time back, solutions of gold, silver, and platinum have been used with success instead of their oxide; and in this way, a more intimate mixture may be procured, and, consequently, more homogeneous tints.

Black Enamel.—Black enamels are made with peroxide of manganese or protoxide

of iron; to which more depth of colour is given with a little cobalt. Clay alone, melted with about a third of its weight of protoxide of iron, gives, according to Clouet, a fine black enamel.

Violet Enamel.—The peroxide of manganese in small quantity by itself furnishes, with saline or alkaline fluxes, an enamel of a very fine violet hue; and variations of shade are easily had, by modifying the proportions of the elements of the coloured frit. The great point is to maintain the manganese in a state of peroxidation, and, consequently, to beware of placing the enamel in contact with any substance attractive of oxygen.

Such are the principal coloured enamels hitherto obtained by means of metallic oxides; but since the number of these oxides is increasing every day, it is to be wished the new trials be made with such as have not yet been employed. From such researches some interesting results would unquestionably be derived.

Of painting on Enamel.—Enamelling is only done on gold and copper; for silver swells up, and causes blisters and holes in the coat of enamel. All enamel paintings are, in fact, done on either copper or gold.

If on gold, the goldsmith prepares the plate that is to be painted upon. The gold should be 22 carats fine: if purer, it would not be sufficiently stiff; if coarser, it would be subject to melt; and its alloy should be half white and half red, that is, half silver and half copper; whereby the enamel with which it is covered will be less disposed to turn green, than if the alloy were entirely copper.

The workman must reserve for the edge of the plate a small fillet, which he calls the *border*. This ledge serves to retain the enamel, and hinders it from falling off when applied and pressed on with a spatula. When the plate is not to be counter-enamelled, it should be charged with less enamel, as, when exposed to heat, the enamel draws up the gold to itself, and makes the piece convex. When the enamel is not to cover the whole plate, it becomes necessary to prepare a lodgment for it. With this view, all the outlines of the figure are traced on the plate with a black-lead pencil, after which recourse is had to the graver.

The whole space enclosed by the outlines must be hollowed out in *bas-relief*, of a depth equal to the height of the fillet, had the plate been entirely enamelled. This sinking of the surface must be done with a flat graver as equally as possible; for if there be an eminence, the enamel would be weaker at that point, and the green would appear. Some artists hatch the bottom of the hollow with close lines, which cross each other in all directions; and others make lines or scratches with the edges of a file broken off square. The hatchings or scratches lay hold of the enamel which might otherwise separate from the plate. After this operation, the plate is cleansed by boiling it in an alkaline lye, and it is washed first with a little weak vinegar, and then with clear water.

The plate thus prepared is to be covered with a coat of white enamel, which is done by bruising a piece of enamel in an agate or porcelain mortar to a coarse powder like sand, washing it well with water, and applying it in the hollow part in its moist state. The plate may meanwhile be held in an ordinary forceps. The enamel powder is spread with a spatula. For condensing the enamel powder, the edges of the plate are struck upon with a spatula.

Whenever the piece is dry, it is placed on a slip of sheet iron perforated with several small holes, see *fig.* 720, which is laid on hot cinders; and it is left there until it ceases to steam. It must be kept hot till it goes to the fire; for were it allowed to cool it would become necessary to heat it again very gradually at the mouth of the furnace of fusion, to prevent the enamel from decrepitating and flying off.

Before describing the manner of exposing the piece to the fire, we must explain the construction of the furnace. It is square, and is shown to front elevation in *fig.* 721. It consists of two pieces, the lower part *a*, or the body of the furnace, and the upper part *n*, or the capital, which is laid on the lower part, as is shown in *fig.* 722, where these two parts are separately represented. The furnace is made of good fire-clay, moderately baked, and resembles very closely the assay or cupellation furnace. Its inside dimensions are 9 inches in width, 13 inches in height in the body, and 9 in the capital. Its general thickness is 2 inches.

The capital has an aperture or door, *c*, *fig.* 721, which is closed by a fire-brick stopper *m*, when the fire is to be made active. By this door fuel is supplied.

The body of the furnace has likewise a door *n*, which reaches down to the projecting shelf *k*, called the *lib* (*menumière*), whose prominence is seen at *r*, *fig.* 721. This shelf is supported and secured by the two brackets, *r*, *r*; the whole being earthenware. The height of the door *n*, is abridged by a peculiar fire brick *o*, which not only covers the whole projection of the shelf *k*, but enters within the opening of the door *n*, filling its breadth, and advancing into the same plane with the inner surface

of the furnace. This plate is called the hearth; its purpose will appear presently; it may be taken out and replaced at pleasure, by laying hold of the handle in its front.

Below the shelf is a square hole, *u*, is seen, which serves for admitting air, and for extracting the ashes. Similar holes are left upon each side of the surface, as is shown in the ground plan of the boat, *fig. 722*, at *u*.

On a level with the shelf, in the interior of the furnace, a thin fire-tile rests, perforated with numerous small holes. This is the grate represented in a ground view in *fig. 720*. *Figs. 723, 724, 725*, represent, under different aspects, the muffle. *Fig. 723* shows the elevation of its further end; *fig. 724* its sides; and *fig. 725* its front part. At *x*, *fig. 722*, the muffle is seen in its place in the furnace, resting on two bars of iron, or, still better, on ledges of fire-clay, supported on brackets attached to the lateral sides of the furnace. The muffle is made of earthenware, and as thin as possible. The fuel consists of dry beech-wood, or oaken branches, about an inch in diameter, cut to the length of nine inches, in order to be laid in horizontal strata within the furnace, one row only being placed above the muffle. When the fire has attained to a white red heat, the sheet iron tray, bearing its enamel plate, is to be introduced with a pair of pincers into the front of the muffle, and gradually advanced towards its further end. The mouth of the muffle is to be then closed with two pieces of charcoal only, between which the artist may see the progress of the operation. Whenever the enamel begins to flow, the tray must be turned round on its base to insure equality of temperature; and as soon as the whole surface is melted, the tray must be withdrawn with its plate, but slowly, lest the vitreous matter be cracked by sudden refrigeration.

The enamel plate, when cold, is to be washed in very dilute nitric acid, and afterwards in cold water, and a second coat of granular enamel paste is to be applied, with the requisite precautions. This being passed through the fire, is to be treated in the same way a third time, when the process will be found complete. Should any chips happen to the enamel coat, they must be widened with a graver, and the space being filled with ground enamel, is to be repaired in the muffle. The plate, covered with a pure white enamel, requires always to be polished and smoothed with sandstone and water, particularly if the article have a plane surface; and it is then finally glazed at the fire.

The painting operation now follows. The artist prepares his enamel colours by pounding them in an agate mortar, with a pestle of agate, and grinding them on an agate slab, with oil of lavender, rendered viscid by exposure to the sun in a shallow vessel, loosely covered with gauze or glass. The grinding of two drachms of enamel pigment into an impalpable powder will occupy a labourer a whole day. The painter should have alongside of him a stove in which a moderate fire is kept up, for drying his work whenever the figures are finished. It is then passed through the muffle.

The following was the process adopted by Henry Bone, R. A., and his son, the late Henry Pierce Bone, who have produced the largest enamels ever painted; and beyond the time and consequent expense there appears no practical limit to the size of enamel paintings.

Preparing the plate.—For small plates (up to two inches long) pure gold is the best material. Silver (quite pure) is also used, but is apt to get a disagreeable yellow colour at the edges by repeated firings. For larger sizes, copper is used. The copper

should be annealed until quite free from spring, and then cleaned with dilute sulphuric acid (one part acid, four water), and shaped in a wooden mould, afterwards used in making the plate, so as to produce a convex surface varying according to the size of the plate, taking care that the shaping does not reproduce the spring in the copper, in which case the process must be repeated. If the plate is not raised in the centre, in the course of repeated firings the corners will rise irregularly, producing undulations over the plate, perfect flatness being next to impossible for large pictures. The copper is then laid face downwards on the convex wooden mould used for shaping, and enamel ground fine with water is spread over it with a small bone spoon; when covered, a fine cloth doubled is pressed gently on it to absorb the water, and then it is smoothed with a steel spatula. This forms the back of the plate, and when fired this part is finished. The copper is now reversed on a convex board the exact counterpart of the other, and covered with white enamel ground fine in the same way as above. The plate is now ready for firing, and after it has been fired and cooled the surface must be ground smooth with a flat piece of flint or other hard substance, with silver sand and water. It must next be covered with a softer and more transparent kind of enamel called *flux*, ground and spread on in the same way as the first enamel, but this time only on the face of the plate. This is fired as before, and when cool the surface must be again ground smooth, and when glazed in the furnace the plate is finished. For the first coat a white solid enamel is used to prevent the green colour from the oxidised copper showing through; the second coat is a softer enamel, to enable the colours used to melt with less heat.

Firing.—The plate is placed on a planche of firestone, or well baked Stourbridge clay, supported on a bed of whiting, thoroughly dried in the furnace, the exact shape of the plate as originally made, which must be used in all subsequent firings. After the whiting is formed in the shape of the plate it should be notched with a flat knife

72

a Planche.
b Bed of whiting.

diagonally across, as in the accompanying diagram. The use of this is to produce an effect of diagonal bracing while the plate cools, and experience has shown that it tends considerably to keep the plate in its original shape. When the plate is small (up to three inches in length) it may be annealed for passing into the hot muffle as follows.—The planche bearing the plate may be placed on another planche heated in the muffle and placed in the front of the muffle for a few minutes, until the steam of the plate or the oil of the picture shall have evaporated; it may then be put in the mouth of the muffle and gradually inserted to the hottest part. After firing it should be placed on

another hot planche and allowed to cool gradually. Large pictures require a different arrangement of the furnace. Over the muffle there should be a fixed iron annealing box, with an iron shelf and door. The bottom should be of cast iron about one inch thick. This should be so arranged that when the muffle attains a white heat the bottom of the annealing box should be of a brightish red at the back, and a dull blood red in front. Large pictures should be placed on the bottom of the box before the furnace is lit, and the larger the size of the picture the slower should the furnace be brought to its full heat, so as to allow five or six hours for the largest size, and two or three for smaller plates. When fired the picture should be returned to the shelf of the annealing box, and left there till quite cold, for which purpose large plates require at least twelve hours. The colours used are mostly the same as those prepared for jewelers and glass painters.

Enamelling at the Lamp.—The art of the lamp enameller is one of the most agreeable and amusing that we know. There is hardly a subject in enamel which may not be executed by the lamp-flame in very little time, and more or less perfectly, according to the dexterity of the artist, and his acquaintance with the principles of enamelling.

In working at the lamp, tubes and rods of glass and enamel must be provided, of various sizes and colours.

The enamelling table is represented in fig. 727, round which several workmen, with their lamps, may be placed, while the large double bellows below is set a-blowing by a treadle moved with the foot. The flame of the lamp, when thus impelled by a powerful jet of air, acquires surprising intensity. The bent nozzles or tubes A, A, A, are made of glass, and are drawn to points modified to the purpose of the enameller.

Fig. 728 shows, in perspective, the lamp A of the enameller standing in its position; the blowpipe C is seen projecting its flame obliquely upwards. The blowpipe is adjustable in an elastic cork D, which fills up exactly the hole of the table into which it enters. When only one person is to work at a table provided with several

lamp, he sits down at the same side with the pedal of the bellows; he takes out the other blow-pipes, and plugs the holes in the table with solid corka.

The lamp is made of copper or tin plate, the wick of cotton threads, and either tallow or oil may be used. Between the lamp and the workman a small board or

727

728

sheet of white iron *a*, called the screen, is interposed to protect his eyes from the glare of light. The screen is fastened to the table by a wooden stem, and it throws its shadow on his face.

The enameller's workshop ought to admit little or no daylight, otherwise the artist, not perceiving his flame distinctly, would be apt to commit mistakes.

It is impossible to describe all the manipulations of this ingenious art, over which taste and dexterity so entirely preside. But we may give an example. Suppose the enameller wishes to make a swan. He takes a tube of white enamel, seals one of its ends hermetically at his lamp, and while the matter is sufficiently hot, he blows on it a milk-mash, resembling the body of the bird; he draws out, and gracefully bends the neck; he shapes the head, the beak, and the tail; then, with slender enamel rods of a proper colour, he makes the eyes; he next opens up the beak with pointed scissor; he forms the wings and the legs; finally attaching the feet, the bird stands complete.

The enameller also makes artificial eyes for human beings, imitating so perfectly the colour and the sound eye of any individual as to render it difficult to discover that he has a blind and a seeing one.

It is difficult to make large articles at the blow-pipe, those which are 2 or 6 inches become nearly unmanageable by the most expert workmen.

ENAMELLING OF CAST IRON AND OTHER HOLLOW WARE. In September, A. D. 1809, a patent was obtained for this process by Dr. Samuel Hensley Hensley. His specification is subdivided into two parts—

1. The coating or lining of iron vessels, &c., by fusion with a vitreous mass, composed of 6 parts of calcined flint, 2 parts of composition or Cornish stone, 9 parts of litharge, 6 parts of borax, 1 part of argillaceous earth, 1 part of nitre, 6 parts of calx of tin, and 1 part of purified potash. Or, 2dly,

8 parts of calcined flint, 8 red lead, 6 borax, 5 calx of tin, and 1 of nitre. Or, 3dly, 12 of potter's composition, 8 borax, 10 white lead, 2 nitre, 1 white marble calcined, 1 argillaceous earth, 2 purified potash, and 5 of calx of tin. Or, 4thly,

4 parts calcined flint, 1 potter's composition, 2 nitre, 4 borax, 1 white marble calcined, 3 argillaceous earth, and 2 calx of tin.

Whichever of the above compositions is taken, must be finely powdered, mixed, and the vitreous mass is to be ground when wet, sifted, and levigated with water. It is then made into a pap with water or gum water. The pap is smeared or brushed over the interior of the vessel, dried, and fused with a proper heat in a muffle.

Calcined bones are also proposed as an ingredient of the flux.

The fusibility of the vitreous compounds is to vary according to the heat to be applied to the vessel, by using various proportions of the vitreous and fluxing materials. Colours may be given, and also gilding.

The second part of his specification describes certain alloys of iron and nickel, which he coats into vessels, and lines or coats them with copper precipitated from its saline solutions. It also describes a mode of giving the precipitated copper an enamel surface by acting upon it with bone ashes and zinc with the aid of heat.

A factory of such enameled bell-wares was carried on for some time, but it was given up for want of due encouragement.

A patent was granted to Thomas and Charles Clarke on the 25th of May, 1839, for a method of enamelling or coating the internal surfaces of iron pots and saucepans, in

such a way as shall prevent the enamel from cracking or splitting off from the effects of fire. This specification prescribes the vessel to be first cleaned by exposing it to the action of dilute sulphuric acid (sensibly sour to the taste) for three or four hours, then boiling the vessel in pure water for a short time, and next applying the composition. This consists of 100 lbs. of calcined ground flints; 50 lbs. of borax, calcined, and finely ground with the above. That mixture is to be fused and gradually cooled.

40 lbs. weight of the above product is to be taken with 5 lbs. weight of potter's clay; to be ground together in water until the mixture forms a pasty consistent mass, which will leave or form a coat on the inner surface of the vessel about one-sixth of an inch thick. When this coat is set, by placing the vessel in a warm room, the second composition is to be applied. This consists of 125 lbs. of white glass (without lead), 25 lbs. of borax, 20 lbs. of soda (crystals), all pulverised together and vitrified by fusion, then ground, cooled in water, and dried. To 45 lbs. of that mixture, 1 lb. of soda is to be added, the whole mixed together in hot water, and when dry pounded; then sifted finely and evenly over the internal surface of the vessel previously covered with the first coating or composition whilst this is still moist. This is the glazing. The vessel thus prepared is to be put into a stove, and dried at the temperature of 212° Fahr. It is then heated in a kiln or muffle like that used for glazing china. The kiln being brought to its full heat, the vessel is placed first at its mouth to heat it gradually, and then put into the interior for fusion of the glaze. In practice it has been found advantageous also to dust the glaze powder over the fused glaze, and apply a second fusing heat in the oven. The enamel, by this double application, becomes much smoother and sounder.

Messrs. Kenrick, of West Bromwich, having produced in their factory and sent into the market some excellent specimens of enamelled saucepans of cast iron, were sued by Messrs. Clarke for the invasion of their patent rights; but after a long litigation in Chancery the patentees were consulted in the Court of Exchequer. The previous process of cleansing with dilute sulphuric acid appeared by the evidence on the trial to have been given up by the patentees, and it was also shown by their own principal scientific witness that a good enamelled iron saucepan could be made by Hickling's specification. In fact, the formulae by which a good enamel may be compounded are almost innumerable; so that a patent for such a purpose seems to be untenable, or at least most easily evaded. Dr. Ure exposed the finely enamelled saucepans of Messrs. Kenrick to very severe trials, having fused even chloride of calcium in them, and found them to stand the fire very perfectly without chipping or cracking. Such a manufacture is one of the greatest improvements recently introduced into domestic economy; such vessels being remarkably clean, salubrious, and adapted to the most delicate culinary operations of boiling, stewing, making of jellies, preserves, &c. They are also admirably fitted for preparing pharmaceutical decoctions, and ordinary extracts.

The enamel of these saucepans is quite free from lead, in consequence of the glass which enters into its composition being quite free from that metal. In several of the saucepans which were at first sent into the market, the enamel was found on analysis to contain a notable proportion of oxide of lead. In consequence of the quantity of borax and soda in the glaze, this oxide was so readily acted upon by acids that sugar of lead was formed by digesting vinegar in them with a gentle heat.

Enamelled iron saucepans had been many years ago imported from Germany, and sold in London. Dr. Ure had occasion to analyse their enamel, and found that it contained abundance of litharge or oxide of lead. The Prussian government has issued an edict prohibiting the use of lead in the enamelling of saucepans, which are so extensively manufactured in Pritz, Gleiwitz, &c. Probably the German ware sent to England was fabricated for exportation, with an enamel made to flux easily by a dose of litharge.

A suitable oven or muffle for lining or coating metals with enamel may have the following dimensions:—

The outside, 8 feet square, with 14-inch walls; the interior muffle, 4 feet square at bottom, rising 6 inches at the sides, and then arched over; the crown may be 18 inches high from the floor; the muffle should be built of fire-brick, 2½ inches thick. Another arch is turned over the first one, which second arch is 7 inches wider at the bottom, and 4 inches higher at the top. A 9-inch wall under the bottom of the muffle at its centre divides the fire-place into two, of 16 inches width each, and 3 feet 3 inches long. The flame of the fire plays between the two arches and up through a 3-inch flue in front, and issues from the top of the arch through three holes, about 4 inches square. These open into a flue, 10 x 9 inches, which runs into the chimney.

The materials for the enamel body (ground flint, potter's clay, and borax) are first mixed together, and then put into a reverberatory furnace, 6 feet 7 inches long, by

3 feet 4 inches wide, and 12 inches high. The flame from an 18-inch fire-place passes over the hearth. The materials are spread over the floor of the oven, about 6 inches thick, and ignited or fritted for 4 or 5 hours, until they begin to heave and work like yeast, when another coating is put on the top, also 6 inches thick, and fired again, and so on the whole day. If it be fired too much it becomes hard and too refractory to work in the muffle. The glaze is worked in an oven similar to the above. It may be composed of about one-half borax and one-half of Cornish stone (partially decomposed granite) in a yellowish powder procured from the potteries. This is fritted for 10 hours, and then fused into a glass which is ground up for the glaze.

ENAMELLED LEATHER. Leather glazed upon one surface, the so-called enamelling composition being in all respects analogous to the ordinary varnish. Instead of enamelling the grain surface, as is usually done, Mr. Nosster removes that surface by splitting or buffing, and then produces what is called "a finish" upon the surface thus formed, by means of a roller, or glass instrument. The flesh side of the skin may be thus prepared for enamelling, and it is less liable to crack, and the enamel to become cloudy on it than the grain side. See **LEATHER**.

ENCAUSTIC PAINTING. A mode of painting with heated or burnt wax, which was practised by the ancients. The wax, when melted, was mixed with as much colour, finely powdered, as it could imbibe, and then the mass was spread on the wall with a hot spatula. When it became cold the designer cut the lines with a cold pointed tool, and other colours were applied and melted into the former. Many modifications of the process have been employed. Amongst the moderns, the term has been improperly given to some cements, which have nothing of an encaustic character about them.

ENCAUSTIC TILES. See **TILES** and **TERRAZZO**.

ENDOGENESIS. See **EXOGENESIS**.

ENGRAVING, a word derived from *ex*, in, and *typos*, to grave or write, is the art of executing designs or devices, upon metal, stones, and other hard substances. In the common acceptance of the word in the present day, it means the execution of such works on plates of copper or steel, for the purpose of obtaining from them impressions in ink or some other coloured fluid. Engraving, in the widest sense of the term, is the oldest of the fine arts; at least, the Scriptures mention it before any reference is made either to painting or sculpture. In the Book of Exodus, ch. xxxv. v. 29, we read that "Aaron shall bear the names of the children of Israel in the breast-plate of judgment upon his heart;" and again, in the same chapter, Moses is commanded to "make a plate of pure gold, and grave upon it, like the engraving of a signet, Holiness to the Lord." Further on, in the sixth chapter of the same book, Moses speaks of Bezaleel, the son of Uri, as a man "filled with the spirit of God, in wisdom, in understanding, and in knowledge, and in all manner of workmanship; and to devise curious works, to work in gold, and in silver, and in brass, and in the cutting of stones," &c. Of him and of Aholabib it is said,—"There hath he skill with wisdom of heart, to work all manner of work of the engraver." &c. &c. These extracts will suffice to show the antiquity of the art of incising or cutting hard substances; whether or not it had its origin at a period anterior to the time of Moses there is no record, but it is now improbable that the Israelites acquired so much knowledge of the art from the Egyptians during their lengthened captivity, an assumption strengthened by the fact that numerous specimens of hieroglyphic engraving, on metal plates and on stone, have been discovered in Egypt and brought to this country; their dates, however, have not, in all cases, been ascertained with certainty.

It is unnecessary to trace back all that might be written respecting the state of this art among the nations of antiquity in its various applications; but as an example of its adoption for a purpose altogether practical, a passage from Herodotus may be adduced. This historian, referring to a period about 500 years before the Christian era, says:—"Aristagoras exhibited to the king of Sparta a tablet, or plate, of brass, on which was inscribed every part of the habitable world, the land and the rivers;" or, in other words, Aristagoras, who was a native of Ionia, had in his possession a metallic map. Moreover, as it is intended to limit this notice to the art of engraving on steel or copper for printing purposes, we pass over the branches or departments of the art that relate to die-sinking, seal-engraving, and engraving on coins, the latter a common process with the ancient Britons and Saxons, who also, according to the opinion of many modern antiquarians, used to ornament their weapons of war with designs cut by the graving tool.

The transition from all previous methods of engraving, to that which in some degree approximates to what is now practised as the result of the discovery of printing, has been thus described by the late Mr. Landseer, who quotes an earlier writer, Mr. Stuart:—"Soon after the conquest (though, from other information, I think it must have been at the least 250 years from that memorable era) a new species of engraving, entirely

differs from the mingled work of the engraver, goldsmith, and chaser, which had preceded it, was introduced, or invented, in, I judge, of which there is scarcely an old country church of any consequence, but affords some curious specimens, and England more than any other nation in Europe. The brass plates on our old sepulchral monuments are executed entirely with the graver, the shadows being expressed by lines or strokes, strengthened in proportion to the required depth of shade, and occasionally crossed with other lines a second and, in some instances, a third time, precisely in the same manner as a copper plate is engraved that is intended for producing impressions. These engraved effigies are commonly found on the horizontal tombstones which form part of the pavement within the church and the feet of the congregation, which kept the lights bright by friction, filled the incisions with dust, and thus darkened the shades: very neat or exquisite workmanship is not therefore expected; yet many of them bear no small evidence of the abilities of the monks, or other workmen, by whom they were performed. Impressions, technically called "rubblings," are taken from these monumental brasses by antiquarians, for the purpose of illustrating works in archæology. The process is simple enough; a sheet, or sheets, as may be required, of white paper, sufficiently large to cover the brass tablet, are laid upon it, these are then rubbed over with a lump of "sheepmaker's head ball," a composition of wax and lamp-black, which leaves on the paper an impression of the raised portions of the metal.

The fifteenth century, which must always be considered as the dawn of universal light and knowledge, gave to the world the art of printing, and from this invention arose a new era in the art of engraving: the earliest method of printing, both books and illustrations, was, as is described under the article *Wood Engraving*, from engraved blocks or tablets. It seems singular that, though engraving on various metals had been practised long before that on wood, no attempt had ever been made to obtain impressions from the plates; like many other important discoveries, this is said to be the result of accident. Vassari, the historian of Italian art, says that, in the year 1460, Maso, or Thomas Finiguerra, a Florentine goldsmith, chanced to let fall a small engraved plate, on which, as was customary with engravers, he had rubbed a little charcoal and oil, that he might the better see the state of his work, into some melted sulphur, and observing that the exact impression of his engraving was left on the sulphur, he repeated the experiment, by passing a roller gently over it. It was successful, and Finiguerra imparted his discovery to Baldini, also a goldsmith of Florence, by whom it was communicated to others. But the most probable origin of the art of printing from metallic plates, is that which is attributed to the early Italian workers in *niello*, or inlaid modeling work, an art used for ornamenting table utensils, swords, armour, &c.; this art consisted in cutting or engraving the required design on silver, and filling up the incisions with a black composition, said to be made of silver and lead, which, from its dark colour, was called by the artists *niello*, abbreviated by the Italians into *niello*; this mixture, when run into the engraved lines, produced a regular effect of *chiar-oscuro* in the entire work. From these engraved plates or objects, the artists in *niello*, who were the goldsmiths and silversmiths of that period, were accustomed to take impressions, by smoking the metal, and then, after cleaning the smooth surface with oil, impressing upon it a piece of damp paper. From such an origin, or from some other very similar to it, undoubtedly, came the art of chalcography, or plate-printing, and it is equally certain, that the art of engraving with the *burin*, or as it is now called, "line engraving," arose in the workshops of the gold and silversmiths.

The practice of making paper from rags, without which the former art would have proved comparatively useless, had been adopted generally throughout Europe towards the end of the fourteenth century, whereby the chief obstacle to printing was removed.

Not very long after the discovery of plate-printing, the engravers, separating themselves from the manufacturing goldsmiths and chasers, formed themselves into a distinct body, opened schools for pupils, and took up their rightful position among the artists of the time.

Italy and Germany have each contended for the honour of being the first discoverers of the art of printing from engraved plates, but the best authorities give to the former country the priority of claim, though the Germans, to whom the printing press was earliest known, soon surpassed their rivals, both in that art and in engraving; but they have not always maintained the superiority.

The principal Italian engravers, contemporary with, or immediately following Finiguerra, were Baldini, Bonticelli, and Andrew Mantegaa; in Germany, the names of Martin Schöner, who began his career about the year 1460, and engraved his own compositions, Israel von Meibeln, Leydenworf, and Wolgemut, stand prominently forward; but it was not till the commencement of the sixteenth century, that engraving occupied a high position among the arts of either country. Singularly enough, Italy, Germany,

and Holland, produced each an engraver, whose works to this day are held in the highest estimation; while Marc Antonio Raimondi (born at Bologna, in 1486), and Albert Dürer (born at Nuremberg, in 1471), were respectively practising the art in Italy and Germany, Lucas Van Leyden (born at Leyden, in 1491) disputed in the Low Countries the palm with these distinguished competitors. As these artists have ever been considered the patriarchs of engraving, a few words respecting the merits of each may not inappropriately be introduced here.

Travelling to Venice for improvement, Marc Antonio saw there some prints, by Albert Dürer, of the life of the Virgin; these he copied with tolerable fidelity; he soon, however, quitted Venice, and went to Rome, where he made the acquaintance of Raffaele, a large number of whose works he engraved. "The purity of his outlines," says Bryan, "the beautiful character and expression of his heads, and the correct drawing of the extremities, establish his merits as a perfect master of design." His works frequently exhibit a deficiency in reflex light and harmony of *chiar-oscuro*, and he appears to have been ignorant of the principles of rendering local colour, or tints, in the abstract; neither did he attempt, or else was unable, to express the various textures of substances; these are, however, minor defects by comparison, and may easily be excused when the state of art generally at that period is taken into account. "Raffaele," says Landseer, "was Marc Antonio's object; and the blandishments, the splendour, and the variety which would have been indispensably necessary to the translation of Correggio or Titian, were not called for here."

Albert Dürer, the head of the German school of engraving, laboured under disadvantages with which the artists of Italy had not to contend. The latter had frequently, if not constantly, the graceful forms and flowing outlines of antique sculpture made familiar to them, and hence their works exhibit, even from the earliest time, much greater elegance of manner, and refinement in execution, than those of Germany. The engravings by Dürer, whom Landseer supposes to be the first who carried his plates with *aqua-fortis*, partake largely of the stiff, dry, and Gothic manner, peculiar to the country and the period, and which to this day is more or less discernible in German art. If Dürer had been so fortunate as to have had the pictures of Raffaele to engrave, he would doubtless have left the world prints of a very different character than those we now see: we should have had more grace of execution, and freedom of lines, but less originality in the style of execution, and, probably, less vigour. Dürer engraved only his own designs, and his faults or defects were those of his time; but, notwithstanding his Gothic bondage, nothing that has ever appeared in more recent periods, surpasses, in executive excellence, his "St. Jerome seated in a Room," here all the objects are rendered with a fidelity, that only the camera could emulate. That very remarkable and mysterious composition known as "The Death's Head," is also a masterly example of execution: the helmet, with all its pomp of heraldic appendage, and the actual and reflex lights on its polished surface, are characteristically, though minutely, expressed; the skull is accurately drawn, and its bony substance unmistakably described. The head of the Saviour, with its beard and wild abundance of snaky tangled hair, has considerable and well-merited breadth of light and shade; the drapery of the female, quaint as it is in style, is not, as we see it in Dürer's other works, hard, stiff, and formal, but relaxes into freedom and simplicity, and has quite a silky texture; in fact, it approaches very nearly to what we now call "picturesque composition of forms, and light and shade." Dürer's etching appears to have been done in, or etched with the acid, at once. He knew either not to have known, or did not care to practise, the process now adopted, of "sopping out," for the purpose of producing gradation of shade. The admirable wood engravings by this artist are referred to in their proper place.

The works of Van Leyden, the Dutchman, are even more Gothic in taste and style than those of Dürer, with whom he is said to have been intimately acquainted: they exhibit the same amount or degree of stiff, angular drapery, as much, perhaps even more, inattention to grace and dignity of form, without his fertile imagination, his occasional vigour, and his truthful observation of individual nature. His execution is neat and clearly defined, but his plates are deficient in firmness and harmonious effect, and his lines are without variation in substance; those that represent near objects, and those that express objects at a distance, are equally fine and delicate: hence the monotony apparent in his prints. They are almost entirely sacred or legendary subjects, from his own designs; among the finest are "The Temptation of St. Anthony," engraved in 1509, when he was only thirteen years of age; "The Crucifixion," and the "Adoration of the Magi."

It would be beyond the province of this notice to record the progress of the art through the continental schools till it took root in England; yet a short history of its introduction and growth on our soil, may not be considered out of place.

Until the middle of the last century, neither painting nor engraving had attained

any eminence in this country; the latter art, especially, was practised chiefly by foreigners, as Hollar, Simon, Vaillant, Blooteling, &c.: previously to whom we had, of our own countrymen, Faithorne, an admirable engraver of portraits, Payne, White, and one or two others of inferior merit; but, with the exception of Faithorne, none whose works are now held in much esteem. The encouragement afforded by George III., almost as soon as he ascended the throne, to the fine arts generally, and the establishment of the Royal Academy, which offered to artists a position in the country they had never before held, gave an impulse to every section, or branch, of art professed. Hogarth's name had, however, become widely known many years before: his numerous plates, all of them from his own designs, are to this day much sought after, not so much, perhaps, for any especial excellence as examples of fine engravings, as for the talent and genius which the subjects display. "Hogarth composed comedies as much as Moliere," was the remark of Walpole: he died just as art was beginning to be recognised and patronised in England. Francis Vivares, a Frenchman by birth, but long settled in England, where he studied the art under Chatehain, carried landscape-engraving to a high point of excellence; some of his prints after pictures by Claude and Gaspar Poussin, exhibit remarkable freedom in the foliage of the trees, and truth in the texture of the various objects introduced in the landscape. Woollett, born at Maidstone, in Kent, who died in 1783; and Sir Robert Strange, a native of one of the Orkney islands, who died in 1792, advanced the art still further; indeed, it is a question whether engraving has ever found more able exponents than these two distinguished men: the latter engraved several portraits, which have rarely been surpassed at any period in the history of art. The works of both these engravers are characterised by bold and vigorous execution, produced by the combined use of the etching-needle and the graver. Contemporaries with these, or their immediate successors, were Broune, who sometimes worked with Woollett, Bartolozzi, Hall, Booker, Green, Ryland, Watts, Sharp, McAnell, Smith, Barlow, &c.: all aided, by their proficiency, to uphold the honour of the art; while John Landseer, father of the living painter, Raimbach, Eagleheart, P'ye, and John Burnet, — the last two yet with us, — may be regarded as the chief connecting links between the past generation and the present.

Engraving on metal plates may be classed under the following heads: — *Etching, line, mezzotinto, chalk, stipple, and aquatint.* Before describing the processes of working these respective kinds, a notice of the instruments used by the engraver is necessary. These, with some modifications, are employed in all the styles.

The *etching-point, or needle*, is a stout piece of steel-wire inserted into a handle; two or three, varying in thickness, are requisite, and they should be frequently and carefully sharpened. This is best done by turning the needle round in the fingers while rubbing it on a bone, and afterwards on a leather strap prepared with patty powder, or on an ordinary razor-strap, to take off any roughness, and to make it perfectly round.

The *dry-point* is a similar instrument, used for delicate lines: it must be sharpened on the bone till a fine conical point is obtained.

The *graver, or burin*, is the principal instrument employed in engraving: several are required, differing from each other in form, from the extreme *lance* shape to the *square*; the former being used for cutting fine lines, the latter for broad: the graver fits into a handle about five inches and a half long, and it should be well-tempered before using, an operation requiring great care. The angle at the meeting of the two lower sides is called the *belly*, and the breadth of the end, the *face*. To sharpen the former, lay one of the flat sides of the graver on the oilstone, keeping the right arm tolerably close to the side, and rub it firmly; next rub the other in the same way, the face is sharpened by holding it firmly in the hand, with the belly upwards, in a slanting direction; rub the end rather gently on the stone, at an angle of about forty-five degrees, taking care to carry it evenly along until it acquires a very sharp point: this being done, hold the engraver a little more upright to square the point, which a very few rubbings will effect. The graver for *line* work must be slightly turned up, to enable the engraver to run it along the plate; otherwise the first indentation he makes on the metal would cause his instrument to become fixed: the graver for *stipple* should be slightly turned down, to make dots only.

The *scraper*, which should have three fluted sides, is used for taking off the burr left by the action of the needles on the metal.

The *burnisher* is employed to soften lines that have been *bit* in, or engraved too dark, and to polish the plate, or get rid of any scratches it may accidentally have received.

The *dabber* used to lay the *etching-ground* evenly, is made by enclosing a small quantity of fine cotton wool very tightly in a piece of silk, the threads of which should be, as much as possible, of uniform thickness.

There are a few other materials which an engraver should have at hand, but they are not of sufficient importance to be mentioned here; we may, however, point out what is technically called a *bridge*, which is nothing more than a thin board for the hand to rest on; it should be smoothly planed, and of a length and breadth in proportion to the size of the plate; at each end a small piece of wood should be fastened to raise it above the plate when covered with wax. A *blind*, made of tissue-paper stretched upon a frame, ought to be placed between the plate and the light, to enable the engraver to see his work on the metal with greater facility and clearness.

In describing the processes of engraving the various styles enumerated above, little more than a general outline of each method can be given, yet sufficient, it may be presumed, to show the nature of the operation: to narrate all the details that might be included in the subject would supply matter enough for a small volume.

Etching may be classed under two heads; that which is known as *painter's-etching*: the latter was practised to some extent by very many of the old painters, particularly those of the Dutch school; and it has also recently come into fashion with many of the artists of our own day, but more for amusement, however, than for any other purpose; in both cases the method of proceeding is alike. Etching is the result of a chemical process resulting in corrosion of the metal on which the design has been laid down, or transferred, in the following manner. The plate must first be covered with a substance already spoken of as *etching ground*, which may be purchased of most of the principal artists' colourmen, but many engravers make their own: the ancient receipt has been handed to us by Mr. C. W. Sharpe, who has engraved some of the largest steel-plates published recently, as that which he always uses:—

	Parts
Black pitch	1
White wax	1
Burgundy pitch	1
Asphaltum	1
Gum mastic	1

Melt the first three ingredients over a slow fire in a pipkin, then add the other two finely powdered, stirring the whole together all the time; when well mixed, pour it into warm water, and make it up, while warm, into balls: if too soft, a little less wax should be used. Care must be taken not to let the mixture burn during the process of making.

The etching-ground resists the action of the *aqua-fortis*. It should be tied up in a piece of strong silk, and applied thus, which is called *laying the ground*:—Take the plate firmly in a small hand vice; hold it, with the polished face upwards, over a charcoal fire that it may not get smoked, till it is well, but not too much, heated; rub the etching-ground, in the silk, over the plate till it is evenly covered; the wax, melting with the heat, cooes through the silk. To effect a more equal distribution of the ground, take the dabber and dab the plate evenly all over, till it appears of an uniform colour; continue the dabbing till the plate begins to cool, but not to set. The ground is then blackened by being held over the smoke of a candle, or two or three tied together.—wax is far preferable; allow; keep the plate in motion, so that every part be made equally dark, and also to avoid injury, by burning, to the composition; when cold the plate is ready to receive the design. To transfer this, a very correct outline of the subject is made with a black-lead pencil on a piece of thin hard paper; fasten the tracing, or drawing, at the top edge, with its face downwards, on to the etching ground, with a piece of banking-wax, described hereafter, and by passing it through a printing-press—such as is used by plate printers, to whom it should be taken—the drawing is transferred to the ground. The bridge being laid over the plate, the process of etching may now be commenced; the points, or needles, which are used to complete the design, remove the ground from the metal wherever they pass, and expose the latter to the action of the acid during the process of what is termed *biting in*. The needles with the most tapering points should be used for the skies and distances, changing them for others for the foreground, which generally requires broader and deeper lines. Any error that has been made may be remedied, by covering the part evenly with the etching-ground mollified by spirits of turpentine, using a camel's-hair pencil for the purpose; and, when dry, the lines may be re-etched through it.

The next operation is that of *biting in*, performed thus:—A wall or border of *banking-wax* is put round the edge of the plate: this wax, called sometimes *bordering wax*, is made by melting over a slow fire, in a glazed pot, two parts of Burgundy pitch, and one of bees-wax, to which is added when melted, a gill of sweet oil: when cold it is quite hard, but by immersion in warm water it becomes soft and ductile, and must be

applied in this state, it will adhere to the metal by being firmly pressed down with the hand: the object in thus backing up the plate is to prevent the escape of the acid which is to be applied; but a spoon or gutter must be left at one corner to pour off the liquid when necessary. Mr. Fielding, — to whom we are indebted for some of the practical hints here alluded to, availing ourselves, however, of the improvements introduced into modern practice, — recommends the following mixture as the best. — "Procure some strong nitrous acid, and then mix, in a wide-mouthed bottle one part of the acid, with five parts of water, adding to it a small quantity of sal ammoniac, in the proportion of the salt of a barrel-head to one part of acid, when mixed for biting. The advantage of using the sal ammoniac is, that it has the peculiar property of causing the aqua fortis to bite more directly downwards, and less laterally, by which means lines laid very closely together are less liable to run into each other, nor does the ground so readily break up." When the mixture is cool — for the acid becomes warm when first mixed with water — pour it on the plate, and let it continue there till the more delicate lines are preserved to be corroded to a sufficient depth; this will probably be in about a quarter of an hour; sweep off the bubbles as they appear on the plate with a camel-hair pencil, or a feather; then pour off the acid through the gutter at the corner, wash the plate with warm water, and leave it to dry. Next, cover those parts which are sufficiently bitten in with Brunswick black, applying it with a camel-hair pencil, and leave it to dry; again put on the acid, and let it remain twenty minutes or half an hour, to give the next degree of depth required; and repeat this process of *stopping out* and *biting in*, until the requisite depths are all attained; three *bittings* are generally enough for a painter's work. The work is now complete, unless the graver is to be used upon it, and the backing wax may be removed, by slightly warming the margin of the plate; and, finally, wash the latter with a soft rag dipped in spirits of turpentine, and rubbing it with olive oil. If, when the plate is cleaned, the engraver finds that the acid has acted as he wishes, he has secured what is technically termed "a good bite."

Steel plates require another method of *biting-in*, on account of their extreme hardness, and liability to rust; the mode just described is applicable only to copper, the metal generally used by painters for their etchings. For steel plates mix together

	Parts									
Pyrologuenous acid	1
Nitric acid	1
Water	8

This mixture should not be allowed to remain on above a minute; let it be washed off at once, and never use the same water twice; the plate must be set up on its edge, and dried as quickly as possible to avoid rust: the acid may be strengthened where a stronger one is required.

Relighting, a process frequently adopted to increase the depth of that where it is required, or to repair any portion of a plate that has been worn by printing or accidentally injured, is thus performed. The plate must be thoroughly cleaned, all traces of grease removed, by washing it with spirits of turpentine and polished with whiting; it is then, when warmed over a charcoal fire or with a lighted paper, ready for relighting the *ground*; this is laid by using a dabber charged with etching-ground, and carefully rubbing the surface; by this means the surface of the plate is uniformly covered, and the lines already engraved are left clear; any part of the plate that it may not be necessary to re-bite, must be stopped out with Brunswick black, and then the acid may be poured over the whole, as in the first process.

Biting on soft ground is a style of engraving formerly much practised in imitation of chalk or pencil drawings; since the introduction of lithography, however, it has been entirely abandoned. The *soft ground* is made by adding one part of lard to three parts of common, or hard, etching-ground, unless the weather be very warm, when a smaller quantity of lard will suffice; it should be laid on and smoked in the manner already described. Mr. Fielding gives the following method for working on it. — "Draw the outline of your subject faintly on a piece of smooth thin writing paper, which must be at least an inch larger every way than the plate; then damp it, and press it carefully on the ground, and turning the edge over, paste down to the back of the plate; in a few hours the paper will be dry, and stretched quite smooth. Holding your hand on the bridge, take an H or HB pencil, and draw your subject on the paper exactly as you wish it to be, pressing strongly for the darker touches, and more lightly for the delicate parts, and, accordingly as you find the ground more or less soft, which depends on the heat of the weather or the room you work in, use a softer or harder pencil, remembering always that the softer the ground the softer the

pencil" (should be). "When the drawing is finished, lift up the paper carefully from the plate, and wherever you have touched with the pencil, the ground will stick to the paper, leaving the copper more or less exposed. A wheel is then put round the margin, the plate bent in, and if too flexible, rebent in the same way as a common etcher, using hard etching-ground for the white."

Line engraving unquestionably occupies the highest place in the category of the arts; and, taking it as a whole, it is the most suitable for representing the various objects that constitute a picture. The soft, pulpy, and luminous character of flesh; the erect, hard, and metallic character of armour; the graceful folds and undulations of draperies, the twisting, undulating, and luxuriant foliage of trees, with the brilliant yet deep-tinted colour of skies, have by this mode, when practised by the best engravers, been more successfully rendered than by any other. The process of line-engraving is, first, to etch the plate in the manner already described, and afterwards to finish it with the graver and dry point. An engraver's etching differs from a painter's etching in that every part of the work has an unfinished appearance, though many engravers, especially of landscapes, carry their etchings so far as to make them very effective; engravers of historical and other figure subjects, generally do little more than enrich the outlines, and the broad shadowed masses, or *chairs*, of the draperies, the flesh being entirely worked in with the *burin*, or graver; no difficulty can be laid down as to the extent to which the etching should be advanced, as the work of the tool commences, as scarcely two engravers adopt the same plan precisely; each must always depend on the nature of the subject. Neither can it be possible to point out in what particular way the graver should be used in the representation of any particular object; this can only be learned in the school of the master, or by studying the works of the best engravers; as a rule it may be simply said, that in making the incision, or *line*, the graver is pushed forward in the direction required, and should be held by the handle, at an angle very slightly inclined to the plane of the steel or copper plate: the action of the graver is to eat the metal clean out.

Within the last few years an instrument, called a *ruling machine*, has been brought into use for laying in flat lines in skies, buildings, and objects requiring straight, or slightly curved lines: considerable time is saved to the artist by its use, and more even tints are produced than the most skillful hand-work, generally, is able to effect; but to counterbalance these advantages, freedom is frequently sacrificed, and in printing a large number of impressions, the machine will, unless very skilfully ruled in, be apt to wear, or to become clogged with ink, sooner than that which is graved.

Mezzotint engraving is generally supposed to owe its origin to Colonel Ludwig von Siegen, an officer in the service of the Landgrave of Hesse: there is extant a portrait by him, in this style, of Amalia, princess of Hesse, dated 1648. Von Siegen is said to have communicated his invention to Prince Rupert, to whom many writers have assigned the credit of originating it: there are several plates executed by the Prince still in existence. It differs from every other style of engraving, both in execution and in the appearance of the impression, in which the plate yields a most beautiful graving resembling a drawing done in wash of colour, by means of a capillary point, rather than a work executed with any sharp pointed instrument; but a pure mezzotint engraving is rarely produced by the present day, even for portraits; the advantages derived from such a style are soft and supple, of which we shall speak presently, with it, to express the different kinds of texture in objects, have been required no otherwise as almost to make them necessary: this combination is termed the *mezzotint style*. The distinguishing excellences of mezzotint are the rich depth of tints, the softness, an exquisite softness, and the harmonious blending of light and shadow: on the other hand, its great defect is the extreme coldness of the high lights, especially where they occur in broad masses.

The instruments used for this kind of work are, *burnishers*, *scraper*, *shading tool*, *roulettes*, and a *cradle*, or *rocking tool*. The burnisher and scraper differ in form from those already described: the roulette is used to darken any part where the surface has been scraped away too much. It ought to be of different sorts: the cradles of the same form as the shading tool, and is used for the purpose of laying ground.

The operation of engraving in mezzotint is precisely the opposite of that adopted in all other styles: the process in the latter is from light to dark, in the former from dark to light, and is thus effected. A plate of steel or copper is indented all over its face by the *cradle*, an instrument which is a wheel with a round or serrated edge, by which a *hurr* is raised on every part in such a quantity that it is filled in with ink, and printed: the impression would exhibit a uniform mass of deep black: this operation is called *laying in the ground*; it is performed backwards, the cradle to and fro, and the direction, or *grain*, as the engravers call them, is determined by a plan, or *scale*, that enables the engraver to pass over the plate in about any number

of directions without repeating any one of them. When an outline of the subject has been first etched in the ordinary way before the ground is laid, the engraver proceeds to scrape away, and then burnish the highest lights, after which the next lightest parts are similarly treated, and the process is repeated after this manner till the work is finished; the deepest shades are produced from the ground that is left untouched. There is, however, no style of engraving for the execution of which it is so difficult to lay down any definite rules, for almost every engraver has his own method of working.

Chalk or stipple engraving, for the terms are synonymous, is extremely simple. The plate has first to be covered with the etching ground, and the subject transferred to it in the ordinary way: the outline is then laid in by means of small dots made with the stipple graver; all the darker parts are afterwards etched in dots larger and laid closer together. The work is then bitten in with the acid; and the ground being taken off, the stipple graver must again be taken up to complete the operation; the light parts and the dark are respectively produced by small and large dots laid in more or less closely together. Stipple is well adapted for, and is often used in, the representation of flesh, when all the other parts of the subject are executed in line: hence it is very frequently employed in portraiture, and in engravings from sculpture. *Chalk engraving* is simply the imitation of drawings in chalk, and is executed like stipple, only that the dots are made with less regularity, and less uniformity of size; in the present day, the two terms are generally considered as expressing the same kind of work.

Aquatint engraving, which represents a drawing in Indian-ink or bistre even more than does mezzotint, has been almost entirely superseded by lithography, and still more recently by chromo-lithography; and there seems little probability that it will ever come into fashion again. This being the case, and as any detailed description of the mode of working would, to be of any service, occupy a very considerable space, it will, doubtless, be deemed sufficient to give only a brief outline of its character and of the mode of operation; this we abbreviate from the notice of Mr. Fielding, formerly one of our most able engravers in aquatint. The process consists in pouring over a highly polished copper plate a liquid composed of resinous gum, dissolved in spirits of wine, which latter, evaporating, leaves the resin spread all over the plate in minute grains that resist the action of the aquafortis, which, however, corrodes the bare surface of the copper that is left between them: this granulated surface is called a *ground*. The ground having been obtained, the margin of the plate should be varnished over, or stopped out, and, when dry, the subject to be aquatinted must be transferred to the plate, either by tracing or drawing with a soft black-lead pencil, which may be used on the ground with nearly the same facility as paper; if the former method be adopted the tracing must be carefully fastened down to the copper by bits of wax along the upper edge. A piece of thin paper, covered on one side with lamp-black and sweet oil, is placed between the tracing and the ground, with the coloured side downwards, and every line of the subject must be passed over with the tracing point, using a moderate pressure. The tracing being finished and the paper removed, a wall of prepared wax, about three quarters of an inch high, must be put round the plate, with a large spout at one corner, to allow of the acid running off.

The plate is now ready for use; and the completion of the design is commenced by stopping out the highest lights on the edges of clouds, water, &c., with a mixture of oxide of bismuth and turpentine varnish, diluting it with spirits of turpentine till of a proper consistence to work freely. Next pour on the acid, composed of one part of strong nitrous acid and five parts of water; let it remain, according to its strength, from half a minute to a minute, then let it run off, wash the plate two or three times with clean water, and dry it carefully with a linen cloth. This process of stopping out and biting in is continued till the work is complete; each time the aquafortis is applied a fresh tint is produced, and as each part successively becomes dark enough it is stopped out; in this manner a plate is often finished with one ground taken in ten or twelve times. We would recommend those who may desire to become thoroughly acquainted with this very interesting yet difficult mode of engraving in consult Fielding's *Art of Engraving*.

A few remarks explanatory of the method of printing steel or copper plates seem to be inseparable from the subject. The press used for the purpose consists of two cylinders or rollers of wood, supported in a strong wooden frame, and movable at their axis. One of these rollers is placed just above, and the other immediately below, the plane or table upon which the plate to be printed is laid. The upper roller is turned round by means of cogged wheels fixed to its axis. The plate being inked by a printer's ink-roller, an operation requiring great care, the paper which is intended to receive the impression is placed upon it, and covered with two or three folds of soft woollen stuff

like blanketing. These are moved along the table to the spot where the two rollers meet; and the upper one being turned by the handle fixed to the fly-wheel, the plate passes through it, conveying the impression as it moves; the print is then taken off the plate, which has to undergo the same process of inking for the next and every succeeding impression. The *proofs* of an engraved plate are always taken by the most skilful workmen in a printing establishment; in the principal houses there are generally employed from two to six men, according to the amount of business transacted, whose duty it is to print proof impressions only; they are called *provers*. A careful, steady workman is not able to print more than from 180 to 200 good ordinary impressions from a plate, the subject of which occupies about seven inches by ten inches, even in what is considered a long day's work, that is, about fourteen hours; the *prover*, from the extreme care required in inking the plate, and from the extra time occupied in wiping it, and preparing the India-paper, will do from thirty to forty, according as the subject of the plate is light or heavy. This difference in the cost of production, taking also into account that the *proofs* are worked off before the plate has become worn, even in the least degree, and that very few proofs, compared with the ordinary prints, are generally struck off, is the reason why they are sold at a price so much greater than the latter.

Notwithstanding the vast multiplication of engravings within the last few years, it is generally admitted, by those best acquainted with the present state of the art, that it is not in a healthy condition. The highest class of pictorial subjects—history, and the highest style of engraving—line, have given place to subjects of less exalted character, and to a mixed style of work, which, however effective for its especial purpose, is not pure art. The pictures by Sir E. Landseer have gained for engravings of such subjects a popularity that has driven almost everything else out of the field, and have created a taste in the public which is scarcely a matter of untalented congratulation. We have engravers in the country capable of executing works equal to whatever has been produced elsewhere at any time, but their talents are not called into requisition in such a way as to exhibit the art of engraving in its highest qualities. Publishers are not willing to risk their capital on works which the public cannot appreciate, and hence their windows are filled with prints, the subjects of which, however pleasing and popular, are not of a kind to elevate the taste; while the conditions under which engravers generally are compelled to work, offer but little inducement for the exercise of the powers at their command. Engraving on copper is in the present day but rarely attempted; formerly nothing else was thought of; now the demand for engraving is so great that copper, even aided by the electrotypes, is insufficient to meet its requirements. In consequence of the comparatively small number of impressions which it yields, a copper-plate will seldom produce more than 500 or 600 good prints; we have known a steel, with occasionally retouching, produce more than 30,000, when well engraved, and carefully printed; very much depends on the printer, both with regard to the excellence of the impression and the durability of the plate. The public demand is for prints both large and cheap, and to obtain this result, the engraver is too often obliged to sacrifice those qualities of his art which under other circumstances his work would exhibit. Such is the state of engraving with us now. There are few, even of the best artists we have, who by their utmost efforts can earn an income equal to that of a tradesman in a small but respectable way of business. This is an evil to be deplored, for it assists to deteriorate the art by forcing the engraver to labour hard for a maintenance, instead of placing him in a position that would enable him to exalt the art and his own reputation at the same time.

A process of depositing steel upon an engraved copper-plate has recently been brought over to this country from France. M. Joubert, a French engraver long settled in England, has introduced it here; he has informed us that a copper-plate thus covered may be made to yield almost any number of impressions, for as the steel coating becomes worn it can be entirely taken off, and a new deposit laid on without injury to the engraving, and this may be done several times; M. Joubert has repeated the experiment with the most satisfactory results. He thus describes his process in a communication made to the Society of Arts, and printed in their journal—

"If the two wires of a galvanic battery be plunged separately into a solution of iron, having ammonia for its basis, the wire of the positive pole is immediately acted upon, while that of the negative pole receives a deposit of the metal of the solution—this is the principle of the process which we have named 'acierage'."

"The operation takes place in this way:—By placing at the positive pole a plate or sheet of iron, and immersing it in a proper iron solution, the metal will be dissolved under the action of the battery, and will form an hydrochlorate of iron, which, being combined with the hydrochlorate of ammonia of the solution, will become a bichloride of ammonia and iron; on a copper plate being placed at the opposite pole and

known as the *electrotype*, if the solution be properly saturated, a deposit of iron, bright and perfectly smooth, is thrown upon the copper plate, from the principle:—

"Water being composed of hydrogen and oxygen:

"Salt ammonia being composed of:—

"1st. Hydrochloric acid containing chlorine and hydrogen;

"2nd. Ammonia, containing hydrogen, nitrogen, and oxygen.

"The water is decomposed under the galvanic action, and the oxygen fixes itself on the iron plate, forming an oxide of iron; the acid hydrochloric of the solution acting upon this oxide becomes a hydrochlorate of iron, whilst the hydrogen precipitates itself upon the plate of the negative pole, and, unable to combine with it, passes up to the surface of the solution as bubbles.

"My invention has for its object certain means of preparing printing surfaces, whether for intaglio or surface printing, as to give them the property of yielding a considerably greater number of impressions than they are capable of doing in their ordinary or natural state. And the invention consists in covering the printing surfaces, whether intaglio or relief, and whether of copper or other soft metal, with a very thin and uniform coating of iron, by means of electro-metallic or galvanic processes. And the invention is applicable whether the device to be printed from be produced by engraving by hand, or by machinery, or by chemical means, and whether the surfaces printed from be the original, or an electrotype surface produced therefrom. I will remark that I am aware that it has been before proposed to coat type and stereotypes with a coating of copper, to enable their surfaces to print a larger number of impressions than they otherwise would do; I therefore lay no claim to the general application of a coating of harder metal on to the surface of a softer one, but my claim to invention is confined to the application of a coating of iron by means of electricity on to copper and other metallic printing surfaces.

"In carrying out the invention I prefer to use that modification of Grove's battery known as Bunsen's, and I do so because it is desirable to have what is called an *intensity arrangement*. The trough I use for containing the solution of iron in which the engraved printing surface is to be immersed in order to be coated is, lined with glass or porcelain, and it is 45 inches long, 22 inches wide, and 18 inches deep. In proceeding to prepare for work, the trough, whether of the size above mentioned or otherwise, is filled with water in combination with hydrochlorate of ammonia (sal ammoniac) in the proportion of one thousand lbs. by weight of water to one hundred lbs. of hydrochlorate of ammonia. A plate of sheet iron, nearly as long and as deep as the trough, is attached to the positive pole of the battery and immersed in the solution. Another plate of sheet iron, about half the size of the other, is attached to the negative pole of the battery, and is immersed in the solution, and when the solution has arrived at the proper condition, which will require several days, the plate of iron attached to the negative pole is removed, and the printing surface to be coated is attached to such pole, and then immersed in the bath till the required coating of iron is obtained thereon. If, on immersing the copper plate in the solution, it be not immediately coated with a bright coating of iron all over, the bath is not in a proper condition, and the copper plate is to be removed and the iron plate attached and returned into the solution. The time occupied in obtaining a proper coating of iron to a printing surface varies from a variety of causes, but a workman after some experience and by careful attention will readily know when to remove the plate from the solution; and it is desirable to state that a copper plate should not be allowed to remain in the bath and attached to the negative pole of the battery after the bright coating of iron has begun to show a lustrous appearance at the edges. Immediately on taking a copper plate from the bath or at any time to be observed in washing off the solution from all parts, and this I believe may be most conveniently done by causing jets of water freely to strike against all parts of the surface. The plate is then dried and washed with spirits of turpentine, when it is ready for being printed from in the ordinary manner.

"If an engraved copper plate be prepared by this process, instead of a comparatively limited number of impressions being obtained and the plate wearing out gradually, a very large number can be printed off without any sign of wear in the plate, the iron coating being actually; the operation of coating can be repeated as many times as required so that almost an unlimited number of impressions can be obtained from one plate, and that a copper one.

"This process will be found extremely valuable with regard to electrotype plates and also for photographic plates, and they can be so protected as to acquire the durability of steel, and moreover, for a steel plate will require repairing from time to time, these will not, but simply recasting them whenever it is found necessary; by these means one electrotype copper plate has yielded more than 12,000 impressions, and was found quite unimpaired when examined minutely."—J. D.

ENGRAVING ON WOOD. The art of wood engraving is so intimately connected with the block-print, that it is impossible to sever the one from the other, inasmuch as the earliest books were printed from large woodcuts, the figure, page, text, and illustration being engraved in one and the same block. Hence the term "block-books" given to these ancient works. The impression from these engraved pages is generally taken in a thin ink, sometimes of a brown hue, which occasionally spreads or bleeds on the lines or letters, and the printing is generally supposed to have been effected by friction on the back of the discoloured paper laid on the inked lines, the sheets so printed were afterwards pressed back to back, and thus formed consecutive pages of the volume. Such books originated from the large wood-cuts of a devotional character, which, in the early part of the 15th century, were spread by the clergy among the common people, perhaps to counteract the evil produced by the use of playing cards, which were also printed in large sheets of cuts, and severed afterwards; but on this point typographical antiquaries are not agreed, as data and other evidence are wanting to enable us to fix either time, or place, to these early productions. The earliest wood-cut bearing a date is that belonging to Earl Spencer, and representing St. Christopher carrying the Saviour across an arm of the sea; it has two lines of text beneath it, and the date 1423 thus expressed "m^o cccc^o xx^o ter^o." The British Museum is possessed of some very early single-leaf wood-cuts, one representing Christ before Pilate, is executed in black line outline, the figures are very large, and retain the characteristic features of the drawings of the manuscripts of the 14th century. Another undated cut is one of those fine full-page illustrations which the schoolmen of that early day delighted in constructing; it is termed *Turris Sapientie*, every tower of which is inscribed with the name of some moral virtue, the foundation buttresses being prudence, fortitude, justice, and temperance; the windows which give it internal light being discretion, religion, devotion, and contemplation. Another representing the seven ages of man, is supposed to be a work of the middle of the 15th century. It was found pasted inside the covers of an old book, a fragment which has preserved many specimens of old engraving which would else have been lost. On the opposite cover is a fragment of another large cut, representing the Virgin with St. Joachim and St. Anne. The St. Christopher above named was discovered in the cover of a volume in the convent library at Bamberg, in Saxony. All these old wood-cuts, as well as the block books, are generally decorated with flat tints of coarse colour, supposed to have been done with stencil plates, such as the card painters used on some occasions; but evidently rudely executed by hand in oil. They are all precisely of the kind to attract the uneducated eye, and to this day similar coarse prints are used by the clergy to aid the devotions of the peasants of the Germanic nations.

The most celebrated of the block books is that termed the *Biblia Pauperum*. Each page is divided by architectural compartments into three subjects, from the Old and New Testaments, selected to form "parallel passages" of sacred writ, above and below are other compartments with heads of the prophets, and in the margins of woodcuts, or open scrolls, are explanatory inscriptions. The page measures 10 inches by 7½, and is one of the most valuable works of its class; but it exhibits very small claims to attention as a specimen of art, certainly less than the *Canticus Cantabrum*, each page of which is divided horizontally into two pictures, with eight descriptive lines on scrolls; or the *Apocalypse's Sancti Johannes*, which is similarly arranged, and in both of which we occasionally find much power of drawing and ability of grouping. The dates of these books can only be conjecturally given, but they are probably contemporary with the St. Christopher, or but a few years later. Judging from general characteristics the *Apocalypse* seems to be the earliest. The figures are executed entirely in outline, with no attempt at shadows, which appear sparingly on the St. Christopher, and are very freely introduced in the *Canticus* and still more abundantly in the *Biblia Pauperum*. These effects are always produced by a series of short lines laid parallel to each other, nor is any attempt made to enrich the unaccredited character of the work by crossing the lines, as in more modern engraving. The *Biblia*, which has excited so many historians as to the place where printing first had birth, has included many doubts concerning the country where these old block-books were fabricated; but from the armorial bearings which appear on the shields of some figures in the *Canticus*, Germany seems to be the country where that series was designed, probably

* Much interest was excited some few years ago by the discovery of a cut in the library at Florence apparently bearing an earlier date, but exact years and months are proved that one of the cuts in the book has been omitted, this makes just one hundred years difference in its age. But the date there almost is quite in accordance with the general character of the design and execution of the cut, which, on the contrary, do not at all agree with the early date assigned to it.

† Among them is the double-headed eagle of Austria, the black eagle of Germany, the three crowns of Bohemia, the cross-arms of Habsburg, the arms of Wurtemberg, Nymphenburg, and others.

Flanders or Holland may claim the *Bible Pauperum*, which does not bear equal traces of refinement in art. The *Speculum Humane Salvationis* has been claimed for Laurence Coster of Haarlem. This book was a combination of block-book and movable type, having large cuts across the top of each page, divided by columns into two subjects, with movable types beneath. It is not unusual to meet with wooden pages of type alone at this period; and books with such pages, or with the addition of wood cuts, were produced by the old engravers after the invention of movable types; but, as metal-cast letters speedily usurped the place of the wooden ones, the wood engravers seem to have soon confined themselves to the pictorial branch of the art.

The love of pictorial illustrations of narrative history gave a permanence to the art of wood engraving, and the works printed in Italy, as well as those introduced into England by Caxton, were adorned with cuts. They are, however, of the rudest kind, with broad heavy lines, and were most probably produced from coarse pen drawings made on the surface of the wood, and mechanically cut by the engraver. Toward the close of the fifteenth century "cross-hatching" (as lines of shadow crossing each other are technically termed) is first seen, and in the Nuremberg Chronicle, 1493, they are freely used. The designers and engravers of these cuts, perceiving the effect, which may be so readily obtained in wood engraving, by leaving the wood untouched with the graver for solid masses of shadow, have availed themselves of it, and given stronger effect to their cuts thereby. Michael Wohlgemuth and William Pleydenwurff were the designers employed; the former artist was the master of Albert Durer, who ultimately raised wood engraving to the highest point of excellence.

Durer's first great work was a series of sixteen large cuts illustrative of the Apocalypse. They were published in 1498, and attracted great attention from the vigour and strange originality of their design, and the artistic character of their treatment. In 1511 another series of cuts was published at Nuremberg by Durer, illustrative of the Apocryphal Life of the Virgin. They evidence the great improvement which the artist had made during the interval, and are certainly the finest wood cuts which had ever been executed up to that period; but they are eclipsed by the series of eleven large cuts published soon after, representing scenes in the Passion of Christ; and which may be fairly considered triumphs of the art of wood-engraving, unsurpassed in design and execution by any successors. The art had now become appreciated wherever it was known, and a host of wood engravers found employ in Nuremberg, cutting the designs of Durer, Hans Horgmair, Hans Schaufelein, and other artists; who found no lack of patronage in the old imperial city, for the Emperor Maximilian I., extremely employed them in various works illustrative of his real or fancied exploits.*

So important was this royal patronage, that the engravers set no bounds to the size of the works they attempted, and hit upon the plan of joining one block of wood to another, until in the engraving representing the triumphal arch in honour of this emperor, a wood-cut was completed in this way, measuring ten feet by nine. The size is, however, not its only claim to attention, for it is throughout designed and engraved with the utmost care and beauty.

In all these cuts of the great masters of the art of wood-engraving, we only find the name of the designer recorded; thus, Durer, and others of his era, whose names occur on cuts, were the designers and draughtsmen on the wood; but the engraver was considered in the light of a mechanic, and, except in a very few instances, his name was not displayed. To fully understand this, it is necessary here to explain the whole process of wood engraving at this time. A block of wood being prepared from a perpendicular cutting of pear-tree, upon the surface was made a drawing, in which every line was delineated with pencil or red-pen, exactly as the cut was ultimately to appear; the intervening spaces of plain wood between every line were then cut away; and in this manual dexterity consisted the whole merit of the engraver. The abundance of cross-hatching so constantly found in old wood cuts, is explained by the fact of this being the easiest and best mode for the draughtsman to employ in getting his effects of light and shade; the extreme labour it involves to the engraver not being considered; but when it is understood that each minute space has to be cut down from each angle of the lines, and the centre entirely cleared out, some idea may be formed of the labour required, when thousands of such squares occur on some of Durer's large cuts, independent of other work. The backs of some of these old blocks, particularly those in the Triumphs of Maximilian, are marked with the names of the engravers, and there is proof that women practised the art; but it is not at all likely

* Such were the efforts of the Knight of the Order, under which from the emperor was figured: "The Wolf King," an equally striking picture of his early education and actions, and the magnificent series of cuts, known as "The Triumphs of Maximilian."

that the artists who designed, and drew upon the wood these designs, went through the merely mechanical labour of engraving them.

The great impetus thus given to wood engraving*, kept it prominently before the world during the whole of the sixteenth century, when the presses of the continent continually brought forth a series of volumes remarkable for the beauty of the cuts by which they were illustrated. This practice of the book-trade gave rise to a series of artists known as "the little masters" of the German school, from the small size of their works; among whom the principal who connected themselves with engraving on wood were Virgil Solis, Henry Aldegraver, the two Behaima, Lucas Cruech, Urse Graff, Albert Aldorffer, Jost Amman, and Solomon Bernard.

In Italy, Ugo da Carpi practised with success, from the year 1518, the art of engraving on wood imitations of tinted drawings; an art which originated with the Germans, but which he much enlarged and improved. It consisted in a series of blocks cut to imitate patches of colour, and made to print over each other in gradations of tint, until the chiaroscuro of a drawing was secured; then the coarser and bolder lines defining the whole design were printed over all, and a capital imitation effected of the bold cartoons, consisting of vivid outline and broad washes of tint, and as first sketches for their pictures and frescoes by the artists of that era.

A perfect rage for book illustration seems to have beset the printers soon after the death of Durer. The most prolific artists who supplied their wants, were Jost Amman and Solomon Bernard: the former executed a multitude of designs on every imaginable subject; the latter, equally prolific, devoted himself chiefly to the illustration of sacred or classic literature. The greatest publishers of such books were Simon and Feyerahand, of Frankfurt-on-the-Maine; Jean de Tournes, and Trechsel, of Lyons; and Plantin, of Antwerp. From their presses issued a series of small volumes, which can only come under the generic title of "picture books," for they were got up for the sake of exhibiting the favourite art of wood-engraving, and only contain a few descriptive lines of type beneath each cut. The cuts executed by Amman are all remarkable for correctness of drawing and vigorous effect; those of Bernard are less scholastically correct, but contain more evidence of grace and fancy. The designs of these artists abound in books published between 1550 and 1580; but the most admirable series were executed in a little volume published at Lyons, in 1588, without the name of draughtsman or engraver, the *Simulachres de la Mort*, known among bibliographers as the "*Lyon's Dance of Death*," a collection of cuts which, for minute beauty and perfection of design and execution, are completely unrivalled, and have not been equalled by any modern copyist†. This was the Augustan age of book-illustration, which flourished in popular favour until the close of the sixteenth century, when a minute tameness, in contradistinction to the rigour of the earlier engravers, began to appear, and reached its culmination in such cuts as were given in Nicolay's "*Travels in Turkey*" (Antwerp, 1576).

Titian is said to have furnished designs for various woodcuts, particularly the series of Costumes published at Venice in 1590; and a very large copper cut of the Destruction of Pharaoh and his host, more than four feet long, is said to have been one among many of uncommon size executed from his designs, they were printed on separate blocks, and then pasted together in the manner of wall-papers. One representing the sacrifice of Abraham is remarkable for the variously tinted tints in which it is printed to exhibit gradations of distance.

Wood-engraving, in the early part of the seventeenth century, had sunk from its high estate. The last great artist who had employed himself in connection with the art was Hans Holbein, and we do not find a great name again conjoined with it until the middle of that century, when Rutens employed Jeghers, of Antwerp, to engrave some of his drawings on wood. The generality of woodcuts in books of this era, rival in coarseness the older block-books; the wood-engravers seem to have sunk into mechanics, unassisted by good artists to furnish them with drawings. The art had become vulgarised, its profession a trade, and the demand and supply scarcely better than the requirements of the ballad printer desired. They were ancillary to the commonest uses of the press, and all art speedily vanished from the ena manufactured probably at a very cheap rate for temporary use. Of this kind are the

* Durer's engravings were an exceedingly popular, that they found their way all over Europe. Raphael admitted them in Rome, and was induced to perpetrate his own designs by engraving on the Antonino Baimondi in engrave them on metal under his own superintendence. He prohibited the modern print trade. Durer's designs were so much in request, that Lucas van Leyden imitated them on copper, for sale to such persons as could not perceive the great difference between the original and his false and discoloured copies. Durer was ultimately obliged to apply for legal redress against these pirates.

† The designs have been popularly ascribed to Holbein, and, apparently, with reason. An artist named Hans Lutzelburgher, of Basel, has been supposed to have been the engraver, from the initials H. L. on one of them. By this time it had become usual to append the initials of engravers to woodcuts, as well as those of the designers.

cuts sprinkled through the English books of the time of James and Charles I. It is possible that the printers were supplied with them from Germany and Flanders. It was customary to use woodcuts repeatedly, particularly if merely ornamental; in this way initial letters were reproduced as the stock in trade of the printing-office; and even scenes of adventure, adopted unscrupulously for other events, to which there was the slightest general resemblance.† The names of these "wood-cutters" have not descended to our time; their works are widely scattered over general literature, and it is not until the middle of the century that we meet with any instance of an attempt to arrest the downward progress of the art. Then, as we have previously noted, Rubens, probably anxious to rival Dürer, engaged Christopher Jocher, of Antwerp, to execute, under his own superintendence and at his expense, a series of large drawings made by himself upon the wood. They differ from the style of the earlier masters, and frequently have a confused blotted look in the lines, which produces deep shadows; they possess, however, all that boldness and vigour of treatment for which the great Flemish painter was so deservedly celebrated; but the engraving is coarse and mechanical. Rubens appears to have felt this, and sometimes a tinted block is added over all, with high lights cut upon it, to give softness and brightness to the whole; an idea he may have adopted from the engravers of Italy who succeeded Ugo da Carpi (—, of whom may be honourably mentioned Andrea Andreani, of Mantua, born 1544, died 1620), or from the designs of Lullman engraved by Businck, which were nearly contemporaneous in France.

Though "fallen from its high estate," the art never sank into complete decay, either in England or upon the continent; there were always a few who followed the profession, and aided the printer with such cuts and designs as he might require. The family of the Jagers practised in Antwerp until the end of the century; a clever series of woodcuts illustrative of the history of the Maas was published at Ghent, and executed by Krafft in 1731. In France, the family of Le Sueur were employed through three generations by bookellers; the last, Nicholas, died in 1764; while Papillon, the author of a *Traité de la Gravure en Bois*, had practised the art from the commencement of the century until 1750, and had been patronised extensively by the bookellers of France and Holland; that he counted his cuts by the thousand. In England, H. Kirkhall executed cuts for books, and from 1722 to 1724 a series of 12 block prints, in imitation of Ugo da Carpi's work already alluded to; in this latter art he produced a greater pupil in J. Jackson, who very successfully copied some of the great works of Titian, Paul Veronese, and others, during the years 1738 to 1743; at this time he resided in Venice, after a short sojourn in Paris, where he was occasionally employed as a wood-engraver. Many cuts scattered through English books about the same period bear the initials of F. H. for Francis Hoffman, whose name is engraved in full on a tail-piece, representing cupids surrounding a lighted altar, to be seen in the first edition of *Gulliver's Travels*, 1726, vol. ii. p. 47. An engraver named Water executed some cuts of a much better character than usual about 1760, particularly those in the *Oxford Sausage*; and in Sir John Hawkins's *History of Music* are some of the largest and most ambitious cuts at that time attempted anywhere. They were engraved by T. Hodgson. Three other persons named respectively, W. Pennock, S. Watts, and H. Cole, occasionally devoted themselves to wood-engraving, which seems to have been practised by such copper-plate engravers as devoted themselves to "general work" for the printing trade or the public, and who varied their labours by occasionally engraving shop-bills or door-plates.

There is one great change in the cuts produced during this period, the result of a different style of drawing made for the wood-engravers, and which discarded cross-hatching and its consequent tedious labour, for a tinted or washed drawing which could be cut into a series of lines by the tool, expressing the varied tints more simply and readily. The art of "lowering" or scraping down to a lower level various parts of a cut that should appear light, and so on at the press in its labours, was also practised, and the harder wood of the box tree used. Such was the state of the art when a Northumbrian peasant boy was destined to appear, again draw universal attention to the neglected profession, and found the modern school of wood engraving.

Thomas Bewick was the son of parents engaged in a colliery, who lived at Cherryburn twelve miles west of Newcastle-on-Tyne; he was born in 1733 and passed his

* In the old printing office of Penton in Antwerp, it is reported, was a large quantity of woodcuts, originally engraved for the books he issued at the end of the 16th century, but nearly the entire stock of them had perished.

† The number of impressions a woodcut will yield has never yet been ascertained. The elasticity of wood gives it a great advantage over metal in press-printing; and while copper and steel woodcuts show little sign of wear, many thousands of impressions may be taken by a carefully used wood printer without injury to a woodcut. As an instance with what impurity a bad printer may use a carefully used woodcut, may be mentioned the fact, that the best printers of the middle of the last century occasionally used cuts that had been engraved in the reign of Charles I., and had headed regular bills for more than 120 years.

early years helping his father's labour. His leisure hours were earnestly devoted to the small amount of knowledge a village school could impart; but as a strong love for nature, and for its imitation, soon developed itself in the boy, his father determined to apprentice him to an engraver of Newcastle, Mr. R. Balby, whose work was of that "general" kind undertaken in a busy country town. There he occasionally engraved initials on tea spoons or names on door plates, until, in the second year of his apprenticeship, his master received an application from Dr. Hutton for wood-cut diagrams, such as were then executed in London, to illustrate his treatise on navigation. Balby knew that young Bewick had been making some attempts in this style and he encouraged him to persevere; he did so, and Hutton's book was published in 1770 with Bewick's cuts. The young engraver had many difficulties to contend against, and had even to construct his own tools; among the rest, a double-pointed graver to enable him to cut both sides of a line at once, and so engage its equal thickness throughout. In 1773, he executed a cent and sent it to the Society of Arts, in London, who awarded him a medal; and in the following year he visited London, and was employed by Hodgson, whom we have already noted as the engraver of the cuts in Hawkins's *History of Man*; as well as by H. Cole. There need be little doubt that this visit to the London wood engravers was useful to Bewick, for he must have become by that means acquainted with the usual mode of practising the art, the proper kinds of tools used, and the various things which make the mechanical part of the profession; but he had fortunately formed a style of his own, so very original, and based so firmly on the study of nature, that wood-engraving in his hands became an art presenting many novel and attractive features never visible before. The wood-engravers from the days of Dürer, or from the first invention of the art, depended entirely on the drawings made upon the wood, and did little more than cut away the interstices; but Bewick cut out of the wood a vast deal of that which no draughtsman could so draw; for with the aid of a slightly tinted drawing, he would cut the foliage of trees, the plumage of birds, the texture of animals, or small figures and birds, by the graving tool alone. His dextrous hand was guided by a perfect knowledge of nature, and every line he cut expressed drawing; in this was his great distinction over all other wood engravers; he cut his pictures out of the wood, the others cut the wood out of the pictures.

Bewick disliked London, and speedily returned to his native place. His first work was an illustrated edition of Gay's *Fables*, published in 1779 by T. Saut, a printer of Newcastle, much engaged in the publication of children's books, and such as the travelling chapmen carried in their packs for the edification of the villagers. These cuts bear the earliest traces of that accurate delineation of nature, and minute truthfulness of expression, which ultimately gave his works universal renown. The wild plants and grasses, however minute they are cut, can always be distinguished by the naturalist; the proper foliage of every tree is truthfully cut by his graver; the birds and insects, however minute, are perfect in drawing; and the general effect of his wood cuts artistically powerful. As he fully felt the value of leaving the wood itself to express solid shadow, he had not the timidity which imagines labour to be necessary to success. The little cut of the Fox and the Bramble in this volume is a good illustration of Bewick's mode. Every leaf of the bramble is cut out, white upon black, with the most truthful power of drawing; the spines on the stem of the bramble are visible to the eye; the fern beside it is similarly expressed by cutting the form of its foliage with the most perfect freedom upon the solid block of wood. Each bush has its distinctive leaf. The dogs in the distance are similarly cut out by the graver on a tinted ground; and the few lines which cover the body of the fox entangled in the bramble, express its texture with a spirit which no mere cutting of a drawing placed on wood by a professional draughtsman could ever give. Bewick's cuts are sometimes termed *cuts*, but no elaboration of labour will elevate the coarsest woodcut above these works, for which Bewick obtained but nine shillings each; and the drawing can be expressed by the engraver as perfectly as Bewick could express it.

Assisted by his brother John, the Newcastle engraver issued a series of works devoted to natural history; the best being the *History of British Birds*. Here Bewick's knowledge of nature, and power of expression by means of his graver shone forth conspicuously. His books became equally celebrated for the humorous tail pieces he occasionally introduced replete of wit and original genius. He laboured steadfastly at his art to a good old age. His brother John left Newcastle to reside in London, where he was much employed, but a pulmonary complaint killed him at the early age of thirty-five. He died in 1795. Thomas Bewick lived to the advanced age of seventy-five. He died in 1823, having worked upon a large woodcut only a few days before his death.

The pupils educated by Bewick were few. The best were Charlton Nesbit, John

Clennell, William Harvey, and John Jackson. Nesbit settled in London, and was extensively employed during a long life. Clennell after a while devoted himself to painting. Harvey turned his attention to drawing on wood, and his designs for book illustration may be numbered by the thousand; his best are in Lane's edition of the *Arabian Nights' Entertainments*. Jackson was greatly employed by the publisher of the latter work, Mr. Charles Knight, particularly on the best cuts in the once-famous *Penny Magazine*.

At the early part of the present century, Mr. Robert Branson founded a London school of wood-engravers, of which he was the head. His style was peculiar, unlike Hewick's, though like him he was self-taught. His cuts have more refinement, but less knowledge of nature: his best pupil was John Thompson, who excelled in his best cuts, the refined knowledge of light and shade, with much of Hewick's power of expressing drawing. Samuel Williams was one of the few modern engravers, who made his own drawings upon the wood, and he produced very brilliant effects by frequently leaving the wood in solid masses of black. Drawings for wood engravers were at this time chiefly supplied by artists who devoted themselves to that particular branch of the art; and knew how to design their compositions so that they should best display the peculiarities of wood-engraved effects. Thurston, Crair, and Harvey were the principal artists so engaged.

A large number of wood-engravers, the pupils of the Newcastle and London *ateliers*, helped to supply the booksellers at home and abroad for a considerable number of years. It was the custom, some twenty years ago, for the foreign booksellers, particularly in Paris, to send the blocks across the channel to English engravers to execute; this led ultimately to several settling on the continent, particularly in France and Germany. The French publishers always sent the wood block with the drawing carefully executed on its surface, by a native artist. These drawings were always elaborately executed in pencil, greatly resembling etchings; little was consequently left for the engraver to do, but follow the lines and cut away the spaces; patience hence became the chief virtue of the wood engraver; and it was ultimately found that its exercise produced so certain an effect, that apprentices knowing nothing of art might aid in thus working out good engravings; and the old style of tinted drawing on wood was discarded for this "fac-simile" work; the best draughtsmen among the French and German artists having willingly furnished these drawings, English artists of a higher grade were induced to draw on wood, but they occasionally failed from not clearly understanding the peculiar effects their work should produce, and the characteristics of the art. Generally speaking, wood engravers prefer cutting from the drawings of professional draughtsmen on wood; who generally execute their work with such elaborate precision, that the engraver has nothing more to do than follow their lines; this, however, has made mere mechanism of much modern wood-engraving; and many expensive cuts exhibiting pencilling in crossed and re-crossed lines, occupying wearisome labour, and costing many ill-bestowed sovereigns, can only be classed with such "art" as is devoted to engraving the Lord's Prayer in the compass of a silver penny; and merely produces the same general effect that Hewick would have obtained in a few bold lines.

The great difference between ancient and modern wood engraving consists in this very boldness; and the practice of the art was essentially different in the sixteenth and eighteenth centuries. The old wood engravers cut on large blocks of soft wood, such as pear-tree, the way of the grain; the moderns, on small blocks of the hardest wood they can obtain—the turkey box, and across the grain. The old engravers cut the work downwards with small knives or gouges; the moderns use graters of various widths to cut out the spaces between fine lines, and broader chisels or gouges to clear away the broad spaces of white. Wood engraving is the exact opposite to copper-plate engraving in the mode by which the lines of engraving are produced. The copper-plate engraver produces his lines by cutting into the metal at once, the wood engraver produces his lines in relief cut out of the block of wood; every line he engraves has to be cut by a double operation, by slicing away the wood on each side of it; for though it is recorded that Hewick invented a double cutting fork-shaped graver to cut away both sides of a line at once, no such tool has ever since been used in the profession.

In order to make the whole process of wood engraving clear to the reader, we will now simply describe the production of a wood cut from the time it leaves the timber-merchant, until it is fit for the hands of the printer. The log of box is cut into transverse slices, $\frac{7}{8}$ of an inch in depth, in order that the face of the cut may be on a level with the surface of the printer's type, and receive the same amount of pressure; the block is then allowed to remain some time to dry, and the longer it is allowed to do so the better, as it prevents accidents by warping and splitting, which sometimes happen after the cut is executed if the wood is too green. The slice is ultimately trimmed into a square block, and if the cut be large, it is made in various

pieces strongly clamped and screwed together; and this enables engravers to get large cuts done in an incredibly short space of time, by putting the various pieces into different engravers' hands, and then screwing the whole together. The upper surface of the wood is carefully prepared so that no inequalities may appear upon it, and it is then presented to the draughtsman to receive the drawing. He covers the surface with a light coat of flake white mixed with weak gum water, and the thinner this coat the better for the engraver. The French draughtsmen use an abundance of flake white, but this is liable to make the drawing rub out under the engraver's hands, or deceive him as to the depth of the line he is cutting in the wood. The old drawings of the era of Durer seem to have been carefully drawn with pen and ink on the wood; but the modern drawing being very finely drawn with the pencil or silver point is obliterated easily, and there is no mode of "setting" or securing it. To obviate this danger the wood-engraver covers the block with paper, and tears out a small piece the size of a shilling to work through, occasionally removing the paper to study the general effect, in damp and wintry weather he sometimes wears a shade over the mouth to hinder the breath from riding on the block. It is now his business to produce in relief the whole of the drawing; with a great variety of tools he cuts away the spaces, however minute, between each of the pencil lines; and should there be tints washed on the drawing to represent sky and water, he cuts such parts of the block into a series of close lines, which will, as near as he can judge, print the same gradation of tint. Should he find he has not done so completely, he can re-visit each line with a broader tool, cutting away a small shaving, thus reducing their width and consequently their colour. Should he make some fatal error that cannot be otherwise rectified, he can cut out the part in the wood, and wedge a plug of fresh wood in the place, when that part of the block can be re-engraved. An error of this sort in a wood-cut is a very troublesome thing; in copper engraving it is scarcely any trouble; a blow with a hammer on the back will obliterate the error on the face, and produce a new surface; but in wood, the surface is cut entirely away except where the lines occur, and it is necessary to cut it deep enough not to touch the paper as it is squeezed through the press upon the lines in printing. To aid the general effect of a cut, it is sometimes usual to lower the surface of the block before the engraving is executed in such parts as should appear light and delicate; they thus receive a mere touch of the paper in the press, the darker parts receiving the whole pressure and coming out with double brilliancy. When careful printing is bestowed on cuts, it is sometimes usual to ensure this good effect, by laying thin pieces of card or paper upon the tympan, of the shape needed to secure pressure on dark parts only.

Wood engraving, as a most useful adjunct to the author, must always command a certain amount of patronage. In works like the present, the author is greatly aided by a diagram, which can more clearly explain his meaning than a page of letter-press; and it can be set up and printed with the type, a mode which no other style of art can rival in simplicity and cheapness. The taste for elaborately executed wood engravings may again decrease, as we find it did for nearly two centuries; but it was never a lost art, and never will be, owing to the practical advantages we speak of, unless it be superseded by some simpler mode of doing the same thing hitherto undiscovered. The number of persons who practise wood engraving in London alone, at present is more than 200, and when we consider the quantity done in the great cities of the continent, and the large amount of book illustration in constant demand; the creative power of one single genius — Thomas Bewick — shines forth in greater vigour than ever. — F. W. F.

ENTRESOL. A floor between other floors; a low set of apartments placed above the first floor. The Quadrant, Regent Street, has a good example of the *entresol*. In Italy the term *Mazzanino*, or little middle floor, is used to indicate the same arrangement.

ENVELOPES. The manufacture of envelopes has so largely increased, that the old method of folding them by means of a "*bone folding stick*," although a good workman could thus produce about a day, was not capable of meeting the demand; hence the attempt of several was turned to the construction of machines for folding them. Amongst the most successful are the following.

Envelope folding.—In the envelope folding machine of Messrs. De la Rue & Co., each piece of paper, previously cut by a fly press into the proper form for making an envelope (and having the lithographical stamp or wafer upon it), is laid by the attendant on a square or rectangular metal frame or box, formed with a short projecting piece at each corner, to serve as guides to the paper, and furnished with a movable bottom, which rests on helical springs. A pressure at the end of a curved compound arm which moves in a vertical plane, then descends, and presses the paper down into the box, — the bottom thereof yielding to the pressure; and thereby the four ends or flaps of the piece of paper

are caused to fly up; the presser may be said to consist of a rectangular metal frame, the ends of which are attached to the outer part of the curved arm, and the sides thereof to the inner portion of the arm, so that the ends and sides of the presser can move independently of each other. The ends of the presser then rise, leaving the two sides of it still holding down the paper: two little lapnet pieces next fold over the two side flaps of the envelope; and immediately a horizontal arm advances, carrying a V-shaped piece charged with adhesive matter or cement (from a saturated endless band), and applies the same to the two flaps. A third lapnet presses down the third flap of the envelope upon the two cemented flaps, and thereby causes it to adhere thereto; and then a pressing-piece, of the same size as the finished envelope, folds over the last flap and presses the whole flat. The final operation is to remove the envelope, and this is effected by a pair of metal fingers, with India-rubber ends, which descend upon the envelope, and, moving sideways, draw the envelope off the bottom of the box (the pressing piece having moved away and the bottom of the box risen to the level of the platform of the machine) on to a slowly moving endless band, which gradually carries the finished envelopes away. A fresh piece of paper is laid upon the box or frame, and the above operations are repeated. This machine makes at the rate of 2700 envelopes per hour.

Another machine for the same object, was invented by Mr. A. Remond, of Birmingham, and is that employed by Messrs. Dickinson & Co. The distinguishing feature of this arrangement is the employment of atmospheric pressure to feed in the paper which is to form the envelope, and to deflect the flaps of the envelope into inclined positions, to facilitate the action of a plunger, which descends to complete the folding. The pieces of paper, cut to the proper form, are laid on a platform, which is furnished with a pin at each corner, to enter the notches in the pieces of paper, and retain them in their proper position, and such platform is caused alternately to rise and bring the upper piece of paper in contact with the instrument that feeds the folding part of the machine, and then to descend until a fresh piece is to be removed. The feeding instrument consists of a horizontal hollow arm, with two holes in the under side, and having a reciprocating movement. When it moves over the upper piece of paper on the platform, a partial vacuum is produced within it, by a suitable exhausting apparatus, and the paper is thereby caused to adhere to it at the holes in its under surface by the pressure of the atmosphere. The instrument carries the paper over a rectangular recess or box; and then, the vacuum within it being destroyed, it deposits the paper between four pins, fixed at the angles of the box, and returns for another piece of paper. As the paper lies on the top of the box, the flap which will be undermost in the finished envelope, is pressed by a small bar or presser on to the upper edge of two angular feeders, communicating with a reservoir of cement or adhesive matter, and thereby becomes coated with cement; and at the same time, the outermost or seal flap may be stamped with any required device, by dies, on the other side of the machine. A rectangular frame or plunger now descends and carries the paper down into the box; the plunger rises, leaving the flaps of the envelope upright; streams of air, issuing from a slot in each side of the box, then cause the flaps to incline inwards; and the folding is completed by the plunger again descending; the interior and under surface of such plunger being formed with projecting parts, suitable for causing the several flaps to fold in proper superposition. The bottom of the box (which is hinged) opens, and discharges the envelope down a shoot on to a table below; the feeding instrument then brings forward another piece of paper; and a repetition of the above movements takes place.

EPSOM SALTS. A sulphate of magnesia, consisting of magnesia 16.26, sulphuric acid 32.53, water 51.22. It derives its name from a mineral spring containing the salt at Epsom. It is largely manufactured. See *Dolomite*.

EQUISETIUM. *H. schub.* A family and genus of acetylenaceous plants. See *Dryas* *Rum.*

EQUIVALENTS, CHEMICAL. By this term is understood the proportions in which substances combine with each other to form definite compounds. These proportions are referred to the common standard, hydrogen, which is taken as unity. The limits of this work preclude the possibility of entering into the history of the steps by which the doctrine of equivalents was gradually developed; but it is proper that we should indicate some of the methods by which the equivalents of elements and compounds are ascertained and demonstrated to be correct. But before proceeding it is necessary to define the term equivalent. This is not easy to do, because the theoretical ideas of all chemists are not the same. Suppose, for example, the constitution of water were to be taken as the starting point. On submitting it to the action of the pile, it is immediately observed that the ratio of the two gases evolved is as 1 to 2. One chemist will at once assume that water is a simple binary compound of one equivalent of each of its constituents. But this involves the assumption that the gaseous volume of the equivalent of hydrogen is twice that of

oxygen. The other chemist assuming that one volume of a gas represents an equivalent, considers water to be a ternary compound having the formula H_2O . It is plain that the atom of hydrogen will have only half the value on the second hypothesis that it will on the first, or, what comes to the same thing, the atom of oxygen will be twice as great. If, with some chemists, we consider the volumes of the gases to represent atoms or equivalents, then, water consisting of two volumes of hydrogen and one volume of oxygen, and as by weight water contains 8 parts of oxygen to 1 part of hydrogen, it is plain that 8 parts of oxygen by weight will represent one equivalent, and 1 part by weight of hydrogen will represent 2 equivalents. Consequently 1 equivalent of hydrogen will weigh .5. But to avoid fractional numbers it will (on these assumptions) be more convenient to write the equivalent of hydrogen = 1, and oxygen 16. In this country it is usual to consider the atom of hydrogen as occupying twice the space in the gaseous state of that of oxygen. The atomic weights being, therefore, oxygen 8 and hydrogen 1.

We have said that it is by no means easy to define an equivalent. The difficulty arises not merely from the different aspects under which theoretical chemists regard the elements and their compounds, but also from the practical difficulties attending the determination of the true constitution of some substances. Thus the equivalent of bismuth is assumed by some to be 51 and by others 213; the oxide in the one case becomes BiO , in the other BiO_3 . The first equivalent being only one-third as great as the second. But, it is to be observed, the variations in the theoretical views of chemists are of no consequence, so long as we clearly comprehend the nature of those variations. The relative values or proportions are the same in all cases. It is, in fact, somewhat the same as if one class regarded the avoirdupois pound as made up of sixteen ounces, each ounce weighing 437.5 grains, and the other considered it as consisting of eight ounces, each ounce containing 875.0 grains.

In order to clearly understand the nature of the equivalents as received in this country, it is necessary to remember that there are three relations of volume amongst gases, namely, one, two, and four volumes. The first relation applies solely to elementary gases. The two others apply to elements and compounds. [It is true that the vapour densities of pentachloride of phosphorus, chloride of ammonium, and, perhaps, one or two other substances, appear to differ from this rule, but it is probable that, like sulphur, the vapour densities require to be determined under special conditions of temperature or pressure.] In the table of equivalents the density of the vapours of those substances which are capable of assuming the gaseous states are so placed that the number obtained by experiment may be compared with that deduced from theoretical considerations. In the following table the vapour volumes or combining measures of some of the more important elements are given. We shall see presently the practical value of the information contained in it.

Element.	Combining Measure.	Element.	Combining Measure.
Hydrogen - - -	two volumes.	Oxygen - - -	one volume.
Chlorine - - -	do.	Sulphur - - -	do.
Bromine - - -	do.	Selenium - - -	do.
Iodine - - -	do.	Phosphorus - - -	do.
Fluorine (hypothetical) - - -	do.	Arsenic - - -	do.
Nitrogen - - -	do.	Carbon - - -	do.

It must be remembered that all volatile compounds possess four volume formulae, except a few, which in this country are always written as if possessing a condensation to two volumes; such are carbonic acid, carbonic oxide, sulphurous acid, &c. With the above information it will be easy for any person to calculate the density of any vapour or gas by the aid of the following directions.

To obtain the density of any vapour or gas having a condensation to four volumes, *such as most organic or inorganic compounds*.—Multiply half the density of hydrogen by the atomic weight of the vapour or gas. **EXAMPLE**.—Find the density of hydrobromic acid. The atomic weight of hydrobromic acid is 81. The density of hydrogen is 0.0692, half of which is 0.0346. Then $(0.0346 \times 81 = 2.8026$. Experiment gave 2.73.

To obtain the density of any vapour or gas having a condensation to two volumes. —Multiply the density of hydrogen by the atomic weight of the gas or vapour. **EXAMPLE**.—Find the density of chlorine gas. The atomic weight of chlorine being 35.5, and the density of hydrogen 0.0692, we have by the rule, $0.0692 \times 35.5 = 2.4564$. The density by experiment is 2.44.

To obtain the density of any vapour or gas, having a condensation to one volume. —Multiply twice the density of hydrogen by the atomic weight of the gas or vapour. **EXAMPLE**.—Find the density of the vapour of oxygen. The atomic weight of

oxygen being 8, and twice the density of hydrogen being 0.1354, we have $0.1354 \times 8 = 1.0832$. Experiment has yielded 1.1026.

The above methods of calculating the densities of vapours and gases are those always employed by the writer of this article, and will be found incomparably shorter and more convenient than any other.

It is perfectly plain that, by a simple inversion of the above rules, it is equally easy from the known density of a gas or vapour to calculate its atomic weight. Nevertheless, for the sake of those who are unaccustomed to calculations of this kind, we append the following rules.

To calculate the atomic weight of any gas or vapour having a condensation to four volumes.—Divide the density of the gas by half the density of hydrogen. **EXAMPLE.**—Find the atomic weight of hydrobromic acid gas, the density of which is 2.8026.

$$\frac{2.8026}{0.0346} = 81.000.$$

To calculate the atomic weight of any gas or vapour having a condensation to two volumes.—Divide the density of the gas by the density of hydrogen.

To calculate the atomic weight of any gas or vapour having a condensation to one volume.—Divide the density of the gas by twice the density of hydrogen.

It is plain then that if we are in possession of the atomic weight and vapour volume of any substance, it is easy to determine the density of its vapour or gas. Also, that having the density of the vapour and the vapour volume, it is easy to calculate the atomic weight. If we consider for an instant what is meant by the term density of a vapour or gas, it will appear equally easy to find, from the density of the gas, the weight of 100 cubic inches at the standard temperature and pressure. By the density of a gas is meant the number expressing how much it is heavier or lighter, bulk for bulk, than air. If, therefore, we multiply the density of a gas by the weight of 100 cubic inches of air, at the standard temperature and pressure (—28.100 grains), we immediately find the number required. **EXAMPLE.**—The density of hydrogen is 0.0692 and $0.0692 \times 30 = 2.0760$, or the weight of 100 cubic inches of hydrogen, at a temperature of 60° Fahr., and 30 inches of the barometer.

From what has been said, it is evident that no difficulty exists in determining the equivalents of bodies which can be obtained in a gaseous state. Where the equivalent of a fixed body is to be ascertained, or where it is desired to proceed in a different manner, the method employed must depend upon the nature of the substance. We shall consider three of the most simple and general cases, namely, an acid, an alkali, and a neutral body.

1. *Mode of determining the equivalent of an acid.*—For this purpose it is necessary to analyse a salt, the constitution of which is known. If the base or metallic oxide in the salt is one of which the atomic weight is well established, it is very easy to determine the combining proportion of the acid. We say, as the percentage of oxide is to the percentage of acid, so is the atomic weight of the oxide to the atomic weight of the acid. **EXAMPLE.**—Butyrate of silver has the following composition:—

Oxide of silver	59.487
Butyric acid	40.513
								100.000

We therefore say —

59.487	:	40.513	::	116	:	79.000
Percentage of oxide of silver.		Percentage of acid.		Equivalent of oxide of silver.		Equivalent of the acid.

It must be remembered that the atomic weight so obtained is that of the anhydrous acid, so that one equivalent of water must be added to find the atomic weight of the acid in its ordinary condition. If the equivalent desired be that of a hydrogen gas, the method of proceeding must be slightly modified, but the details need not be given as they are self-evident.

2. *Mode of determining the equivalent of an alkali.*—Several methods present themselves, each possessing certain advantages. Most alkalies, organic and inorganic, form salts well adapted for enabling their atomic weight to be ascertained by analysis. We shall select as an example ammonia, and the salt employed to settle the atomic weight will be the sulphate, which contains:—

Oxide of ammonium	39.40
Sulphuric acid	60.60
								100.00

In the same way that an oxide of known composition is the datum employed to

determine the equivalent of an acid, so, on the other hand, an acid, the formula of which is well established, serves to enable the formula of an alkali to be deduced. We therefore say—

$$\frac{60.60}{\text{Percentage of acid.}} : \frac{39.40}{\text{Percentage of alkali.}} :: \frac{40.00}{\text{Equivalent of the acid.}} : \frac{26.00}{\text{Equivalent of the alkali.}}$$

Most alkalies, especially those derived from the organic kingdom, form well defined and easily crystallisable compounds with some of the metallic chlorides, especially those of gold, platinum, and palladium. These salts are well adapted for enabling atomic weights to be fixed.

2. *Mode of determining the equivalent of a neutral substance.*—Neutral bodies are formed upon so many models or types that no general method can be given for the required purpose. If volatile at moderate temperatures, the density of the vapour can be ascertained, and this is generally sufficient. Salts have their equivalents found by determining the percentage composition, and proceeding as in examples 1 and 2. The equivalent of a metal is found by forming a compound with some substance, the atomic weight of which is well known, such as oxygen or sulphur. The compound is then carefully analysed. **EXAMPLE:**—It has been found that 100 parts of oxide of copper contain

Copper	-	-	-	-	-	-	-	80.00
Oxygen	-	-	-	-	-	-	-	20.00
								100.00

We therefore say:—

$$\frac{20.00}{\text{Percentage of oxygen.}} : \frac{80.00}{\text{Percentage of copper.}} :: \frac{8.00}{\text{Equivalent of oxygen.}} : \frac{32.00}{\text{Equivalent of copper.}}$$

A precisely analogous mode of proceeding may be adopted with chlorides, iodides, &c.

A careful study of the numbers in the following tables will enable us to observe numerous and highly interesting relations subsisting between them. It has been shown by M. Dumas that certain families or groups of elements fall into natural triads, owing to the relations between their atomic weights. With bodies of this kind, it is found that, if the sums of the atomic weights of the extremes of the series be divided by two, we obtain the atomic weight of the middle body; thus:—

	I.		II.		III.
Chlorine	35.5	Sulphur	16.00	Lithium	7.00
Iodine	127.0	Tellurium	64.00	Potassium	39.00
	$\frac{162.5}{2} = 81.25$		$\frac{80.00}{2} = 40.00$		$\frac{46.00}{2} = 23.00$

The triads here are i. chlorine, bromine, and iodine; ii. sulphur, selenium, and tellurium; iii. lithium, sodium, and potassium. Space will not allow of the subject being developed at greater length in this work. The student, interested in this branch of chemistry, will find much information in the papers of Dr. Odling, recently published in the *Journal of the Chemical Society*.

Table of the Equivalents, &c., of the Non-metallic Elements.

NAME.	Symbol.	Equivalent H = 1.	Density as Vapour or Gas.
Bromine	Br	80.00	5.4110
Carbon	C	6.00	0.8220
Chlorine	Cl	35.50	2.4520
Fluorine	Fl	19.00	1.3170
Hydrogen	H	1.00	0.0692
Iodine	I	127.00	5.7627
Nitrogen	N	14.00	0.9713
Oxygen	O	8.00	1.1056
Phosphorus	P	32.00	4.2940
Selenium	Se	40.00	7.6960
Sulphur	S	16.00	2.2140

[NOTE.—The densities of the vapours of carbon, selenium, and fluorine are hypothetical. That of sulphur is usually represented by a number three times as

great as the above, but this is owing to the experiment not having been performed at a sufficiently high temperature.]

Table of the Equivalents of the Metallic Elements.

Name.	Symbol.	Equivalent H = 1	Specific Gravity.
Aluminium	Al	13.67	2.56
Antimony	Sb	129.00	6.70
Arsenic	As	75.00	5.57
Barium	Ba	68.50	4.70
Bismuth	Bi	217.00	9.80
Boron	B	11.00	2.68
Cadmium	Cd	56.00	8.65
Calcium	Ca	20.00	1.55
Cerium	Ce	46.00	
Chromium	Cr	26.27	3.80
Cobalt	Co	25.00	5.87
Copper	Cu	32.00	5.72
Dilysium	D	48.00	
Erbium	E		
Glaucium	G	6.97	
Gold	Au	98.53	19.4 to 19.6
Humbium	H		
Iodine	I	99.56	11.67
Iron	Fe	28.00	7.84
Lanthanum	La		
Lead	Pb	104.00	11.30
Lithium	L	7.00	0.2336
Magnesium	Mg	12.00	1.73
Manganese	Mn	26.00	8.00
Mercury	Hg	100.00	13.60
Molybdenum	M	48.00	5.60
Nickel	Ni	29.50	8.63
Niobium	Nb		
Osmium	Os	99.41	10.0
Palladium	Pd	53.24	11.50
Platinum	Pt	97.00	21.50
Potassium	K	39.00	0.85
Rhodium	Rh	52.16	11.70
Rhenium	Ru	52.11	8.00
Silicon	Si	21.00	
Silver	Ag	108.00	10.47
Sodium	Na	23.00	0.27
Strontium	Sr	44.00	2.54
Tantalum	Ta		
Tellurium	Te	64.08	6.30
Terbium	Tb		
Thorium	Th	59.50	
Tin	Sn	35.00	7.29
Titanium	Ti	24.12	3.28
Tungsten	W	92.00	17.2 to 17.6
Uranium	U	80.00	10.15
Vanadium	V	60.46	
Yttrium	Y		
Zinc	Zn	32.52	6.91
Zirconium	Zr	32.53	

It will be seen, from the above table, that a very considerable number of the equivalents are entire multiples of that of hydrogen. M. Dumas and others have, however, shown by elaborate and conclusive experiments, that the doctrine of the equivalents of all elements being multiples of that of hydrogen is not a law of nature, as, in addition to chlorine, there are several undoubted exceptions. — C. G. W.

EREMACAUISIS. — *slow combustion*. This term has been applied to that constant combination of oxygen with carbon and hydrogen, to form carbonic acid and water, which is unceasingly going on in nature, as is the decay of timber, or the "heating"

of hay or grain put together in a moist state. Perfect dryness, and a temperature below freezing, stops this emanation, or slow condensation.

ERYTHRIC ACID. Characteristic principle of Angola and Madagascar Orchilla weeds (See ORCHILLA.) By macerating the lichen in milk of lime, Stenhouse obtained 12 per cent. of erub. erythric acid. It yields red coloured compounds with ammonia, and also in its combination with hypochlorite of lime. See LICHEN.

ERMINE. See FUR.

ERRATIC BLOCKS. Rounded and weather-worn fragments of the harder rocks, which are found very widely scattered, at great distances from the places from which they are supposed to have been derived. They are generally supposed to have been removed by the transporting power of icebergs and fields of ice.

ESPARTO. A species of rush—the *Stipa tenuissima*—found in the southern provinces of Spain. It is used for making cordage, shoes, matting, baskets, nets, mattresses, sacks, &c. Cables made of esparto are said to be excellent, being light, they float on the surface of the water, and are not therefore so liable as hempen cables to be cut or injured by a foul bottom.—*McCulloch*.

ESSENCE OF SPRUCE is prepared by boiling the young tops of the *Abies nigra*, or black spruce, in water, and concentrating the decoction by evaporation in a water bath.

ESSENCE. See PERFUMERY.

ESSENTIAL OILS. See OILS, FIXED AND ESSENTIAL, and OTTO.

ESSENCE D'ORIENT. The name of a pearly looking matter procured from the May or bleak, a fish of the genus *cypripa*. This substance, which is found principally at the base of the scales, is used in the manufacture of artificial pearls. A large quantity of the scales being scraped into water in a tub, are there rubbed between the hands to separate the shining stuff, which subsides on repose. The first water being decanted, more is added with agitation till the essence is thoroughly washed from all impurities, when the whole is thrown upon a sieve, the substance passes through, but the scales are retained. The water being decanted off, the essence is procured in a viscid state, of a bluish-white colour, and a pearly aspect. The intestines of the same fish are also covered with this beautiful glistening matter. Several other fish yield it, but in smaller proportion. When well prepared, it presents exactly the appearance and reflections of the real pearl, or the finest mother of pearl; properties which are probably owing to the interposition of some portions of this same substance between the laminae of these shelly concretions. Its chemical nature has not been investigated; it putrefies readily when kept moist, an accident which may however be counteracted by water of ammonia. See PEARLS.

ETCHING VARNISH. (*Aetzgrund-Drechselsnuz*, Germ.) Though the practice of this elegant art does not come within the scope of our Dictionary, the preparation of the varnishes, and of the biting menstrua which it employs, legitimately belongs to it.

The varnish of Mr. Lawrence, an English artist resident in Paris, is made as follows: Take of virgin wax and asphaltum, each two ounces, of black pitch and burgundy-pitch, each half an ounce. Melt the wax and pitch in a new earthenware glazed pot, and add to them, by degrees, the asphaltum, finely powdered. Let the whole boil till such time as that, taking a drop upon a plate, it will break when it is cold, on bending it double two or three times between the fingers. The varnish, being then enough boiled, must be taken off the fire, and after it cools a little, must be poured into warm water, that it may work the more easily with the hands, so as to be formed into balls, which must be kneaded, and put into a piece of taffety for use.

Care must be taken, first, that the fire be not too violent, for fear of burning the ingredients, a slight simmering being sufficient; secondly, that whilst the asphaltum is putting in, and even after it is mixed with the ingredients, they should be stirred continually with the spatula; and, thirdly, that the water into which this composition is thrown should be nearly of the same degree of warmth with it, in order to prevent a kind of cracking that happens when the water is too cold.

Preparation of the hard varnish used by Callot, commonly called the Florence Varnish.—Take four ounces of fat oil very clear, and made of good linseed oil, like that used by painters; heat it in a clean pot of glazed earthenware, and afterwards put to it four ounces of nutmeg well powdered, and stir the mixture briskly till the whole be well melted, then pass the mass through a piece of fine linen into a glass bottle with a long neck, that can be stoppered very securely, and keep it for the use that will be explained below.

Method of applying the soft varnish to the plate, and of blackening it.—The plate being well polished and burnished, as also cleansed from all greasiness by chalk or Spanish white, fix a hand-vice on the edge of the plate where no work is intended to be, to serve as a handle for managing it when warm; then put it upon a chafin-dish, in which there is a moderate fire, and cover the whole plate equally with a thin coat of the varnish; and whilst the plate is warm, and the varnish upon it in a fluid state, beat every part of the varnish gently with a small ball or dauber made of cotton

tried up in taffety, which operation smooths and distributes the varnish equally over the plate.

When the plate is thus uniformly and thinly covered with the varnish, it must be blackened by a piece of flambeau, or of a large candle which affords a copious smoke; sometimes two or even four such candles are used together for the sake of despatch, that the varnish may not grow cold, which if it does during the operation, the plate must be heated again, that it may be in a melted state when that operation is performed; but great care must be observed not to burn it, which when it happens may be easily perceived by the varnish appearing burnt and losing its gloss.

The menstruum used and recommended by Turrell, an eminent London artist, for etching upon steel, was prepared as follows:—

Take Pyroligneous acid 4 parts, by measure,
Alcohol 1 part, mix, and add
Nitric acid 1 part.

This mixed liquor is to be applied from 1 to 15 minutes, according to the depth desired. The nitric acid was employed of the strength of 1.25—the doubly aquafortis of the shop.

The *eau forte* or menstruum for copper, used by Callot, as also by Piranesi, with a slight modification, is prepared, with 8 parts of strong French vinegar,

4 parts of verdigris,
4 ditto sea salt,
4 ditto sal ammoniac,
1 ditto alum,
16 ditto water.

The solid substances are to be well ground, dissolved in the vinegar, and diluted with the water; the mixture is now to be boiled for a moment, and then set aside to cool. This method is applied to the washed, dried, and varnished plate, after it has suffered the ordinary action of an aquafortis, in order to deepen and finish the delicate touches. It is at present called the *eau forte à passer*.

ETHER, $\text{C}_2\text{H}_4\text{O}$. (Or, for four volumes of vapour, $\text{C}_2\text{H}_6\text{O}$.) For the nature of four-volume formulae, see the articles EQUIVALENTS, CHEMICAL, and FORMULÆ.) Syn. Sulphuric ether, Oxide of ethyle, Eth. æc or Vinæ ether, &c. &c. By this term is known the very volatile fluid produced by the action on alcohol of substances having a powerful affinity for water.

Preparation on small scale.—A capacious retort with a moderate sized tubulature is connected with an efficient condensing arrangement. Through the tubulature passes a tube connected with a vessel full of spirit, sp. gr. 0.83. The tube must have a stopcock to regulate the flow. A mixture being made of five parts of alcohol of the density given above, and nine parts of oil of vitriol, it is to be introduced into the retort, and a lamp flame is to be so adjusted as to keep the whole gently boiling. As soon as the ether begins to come over, the stopcock connected with the spirit reservoir is to be turned sufficiently to keep the fluid in the retort at its original level.

Preparation on large scale.—The apparatus is to be arranged on the same principle, but, for fear of fracture, may be constructed of cast iron, lined with sheet lead in the part containing the mixture. The chief disadvantage of this arrangement is its opacity, which by it becomes impossible to see the contents of the retort, and therefore not so easy to keep the liquid at its original level. In this case the quantity distilling over must be noted and the flow of spirit into the retort regulated accordingly. The most convenient mode of proceeding is to have a large stone bottle with a tubulature at the side near the bottom (like a water filter) to hold the spirit. A tube passes from the bottle to the retort. It has at the end, near the retort or still, a bend downwards leading into the tubulature. If a glass still be used it must for safety be placed in a sand bath. The distillate obtained, either on the large or small scale, is never pure ether, but contains sulphurous and acetic acids, besides water and alcohol. To remove these, the distillate is introduced, along with a little cream of lime, into a large separating globe, such as that mentioned under HAUNTS. The whole is to be well agitated, and the liquor solution then run off by means of the stopcock. The purified ether still contains alcohol and water, to remove which it should be rectified in a water bath. The fluid will then constitute the ether of commerce. If the second distillation be pushed too far the ether will, if evaporated on the luted, leave an unpleasant after smell, characteristic of impure ether. If wished exceedingly pure, it must be shaken up in the separating globe, with pure water. This will dissolve the alcohol and leave the ether, contaminated only by a little water, which may be removed by distillation with quicklime and redistillation at a very low temperature on a hot water bath.

Pure ether is a colourless mobile liquid, sp. gr. 0.71. It boils at 95° F. The density of its vapour is 9.56 (calculated). Gay-Lussac found it 2.886.

The word ether, like that of alcohol, alcoholide, &c., is now used as a generic term to express a body derived from an alcohol by the elimination of water. Many chemists wrote the formula C_2H_5O , and call it oxide of ethyl in the same manner as they regard alcohol as the hydrated oxide of the same radical. But there is no just reason for departing from the law we have laid down with reference to the formulae of organic compounds. (See EQUILIBRIUM, CHEMICAL.) We shall therefore write ether C_2H_5O . This view has many advantages. We regard, with Gerhardt and Williamson, ether and alcohol as derived from the type water. Alcohol is two atoms of water in which one equivalent of hydrogen is replaced by ethyl; ether is two atoms of water in which both atoms of hydrogen are replaced by that radical. But there are a large class of compound ethers procurable by a variety of processes. These ethers were long regarded as salts in which oxide of ethyl acted the part of a base. Thus, when butyrate of soda was distilled with alcohol and sulphuric acid, the resulting product was regarded as butyrate of oxide of ethyl. The compound ethers are regarded as two atoms of water in which one equivalent of hydrogen is replaced by the radical of an alcohol, and the other by the radical of an acid. In addition to those there are others more closely resembling the simple ethers. They are formed also on the water type, both atoms of hydrogen being replaced by alcohol radicals, but by different individuals. They are called mixed ethers. The following formulae show the chemical constitution of all these various ethers placed for comparison in juxtaposition with their type. —

In the above formulae the first represents the type water. The second common ether, the two equivalents of ethyl replacing the two of hydrogen. In the third, we have a mixed ether, one of the equivalents of hydrogen being replaced by ethyl and the other by methyl. The fourth illustration is that of a compound ether — one of the hydrogens is there replaced by ethyl, and the other by the oxidised radical of butyric acid.

Ether is largely used in medicine and chemistry. In small doses it acts as a powerful stimulant. Inhaled in quantity it is an anæsthetic. It is a most invaluable solvent in organic chemistry for resins, fatty, and numerous other bodies. — C. G. W.

ETHER, ACETIC, is used to flavour silent corn spirits in making imitation brandy; it requires therefore some additional note beyond the other ethers. It may be prepared by mixing 20 parts of acetate of potash, 10 parts of alcohol and 11 of concentrated sulphuric acid; or 16 of the anhydrous acetate, 5 of the acid, and 4 of absolute alcohol; distilling the mixture in a glass retort into a very cold receiver, agitating along with weak potash lye the liquor which comes over, distilling the supernatant ether, and rectifying it by re-distilling over magnesia and ground charcoal.

Acetic ether is a colourless liquid of a fragrant and pleasant taste, of sp. grav. 0.866 at 45° F., boiling at 166° F., burning with a yellowish flame, and disengaging fumes of acetic acid. It is soluble in 8 parts of water.

Acetic ether may be economically made with 3 parts of acetate of potash, 3 of very strong alcohol, and 2 of the strongest sulphuric acid, distilled together. The first product must be re-distilled along with one-fifth of its weight of sulphuric acid; as much ether will be obtained as there was alcohol employed.

ETHIOPS was the name given by the alchemists to certain black metallic preparations. Martial ethiops was the black oxide of iron; mineral ethiops, the black sulphuret of mercury; and ethiops *per se*, the black oxide of mercury.

ETHYLAMINE, C_2H_5N . An exceedingly volatile base, discovered by Wurtz. It is produced in a great number of reactions. Several alkaloids existing in the animal and vegetable kingdoms afford ethylamine on distillation with potash. Its density at 476, is 0.563. It boils at 66° F. It is regarded as ammonia in which an equivalent of hydrogen is replaced by ethyl. — C. G. W.

ETIOLATION. Deprived of colour by being kept in the dark. Celery, sea-hale, and some other plants are purposely bleached or etiolated by excluding the light, this exclusion preventing the formation of chlorophyll, the green colouring matter of leaves.

EUCALYPTUS. The gum tree of the New Hollanders. Mr. Backhouse (*Companion to the Horticultural Magazine*, 1832, p. 132) "We often find large cavities between the annual concentric circles of the trunk filled with a most beautiful red or rich vermilion coloured liquid gum, which flows out as soon as the saw has afforded it an opening. The gum yielded by the *Eucalyptus resinifera* is considered by druggists

as not in the least inferior to the kind which the *pterocarpus* or red sanders wood of India produces.

EUPHOMETRUM, is the name of any apparatus subservient to the chemical examination of the atmosphere. It means a *measure of purity*, but it is employed merely to determine the proportion of oxygen which it may contain. The explosive eudiometer, in which about two measures of hydrogen are introduced into a graduated glass tube, containing five measures of atmospheric air, and an electric spark is passed across the mixture, is the best of all eudiometers; and of these, the eudiometer proposed by Dr. Ure in a paper published by the Royal Society of Edinburgh in 1819 is the most convenient.

EUGENIA. A genus of plants of the order Myrtaceæ, called after Prince Eugene of Savoy.

The most remarkable species of this genus is the allspice, or pimento tree. See **PIMENTO**.

EUKAIRITE. An ore of silver found in a copper mine in Sweden. According to Berzelius it consists of,

Selenium	-	-	-	-	-	-	-	26
Silver	-	-	-	-	-	-	-	38.93
Copper	-	-	-	-	-	-	-	23.95
Earthy matter	-	-	-	-	-	-	-	8.90
Carbonic acid, &c.	-	-	-	-	-	-	-	3.12

EUPHON. A fluid first discovered by Reichenbach in wood tar. All the properties of euphonia agree with the indifferent hydrocarbons found in Refined naphtha. (See **NAPHTHA**, **ROGHEAD**.) Euphonia is so indifferent to the action of acids, that it may be repeatedly treated with concentrated oil of vitriol, or fuming nitric acid, without any action taking place. Its density varies with the boiling point, from 0.634 to 0.740. It is said to be contained among the products of the distillation of rape oil. There is no doubt that these hydrocarbons will, eventually, be of great value in the arts.—C. G. W.

EURITE. A granulous compound of feldspar and quartz, with sometimes garnet. "It generally occurs as veins, or as local masses in other granites, and rarely, I believe, as veins traversing other rocks at a distance from granite. These, therefore are probably veins of segregation, or of injection during consolidation, and not of subsequent formation."—*Jukes's Student's Manual of Geology*.

EVAPORATION (Eng. and Fr.: *Abdampfen*; *Abdunsten*, Germ.) is the process by which any substance is converted into, and carried off, in vapour. Though ice, camphor, and many other solids evaporate readily in dry air, we shall consider, at present, merely the vaporisation of water by heat artificially applied.

The vapour of water is an elastic fluid, whose tension and density depend upon the temperature of the water with which it is in contact. Thus the vapour rising from water heated to 165° F. possesses an elastic force capable of supporting a column of mercury 10.8 high; and its density is such that 80 cubic feet of such vapour contain one pound weight of water; whereas 32½ cubic feet of steam of the density corresponding to a temperature of 212° and a pressure of 30 inches of mercury, weigh one pound. When the temperature of the water is given, the elasticity and specific gravity of the vapour emitted by it, may be found.

Since the vapour rises from the water only in virtue of the elasticity due to its gaseous nature, it is obvious that no more can be produced, unless what is already incumbent upon the liquid have its tension altered, or be withdrawn by some means. Suppose the temperature of the water to be midway between freezing and boiling, viz. 122° Fahr., as also that of the air in contact with it to be the same, but replete with moisture, so that its interstitial spaces are filled with vapour of corresponding elasticity and specific gravity with that given off by the water, it is certain that no fresh formation of vapour can take place in these circumstances. But the moment a portion of vapour is allowed to escape, or is drawn off by condensation to another vessel, an equivalent portion of vapour will be immediately exhaled from the water.

The pressure of the air and of other vapours upon the surface of water in an open vessel, does not prevent evaporation of the liquid; it merely retards its progress. Experience shows that the space filled with an elastic fluid, as air or other gaseous body, is capable of receiving as much aqueous vapour as if it were vacuum, only the rejection of that space with the vapour proceeds more slowly in the former predicament than in the latter, but in both cases it arrives eventually at the same pitch. Dr. Dalton very ingeniously proved, that the particles of aeriform bodies present no permanent obstacle to the introduction of a gaseous atmosphere of another kind among them, but merely obstruct its diffusion momentarily, as if by a species of friction. Hence, exhalation at atmospheric temperatures is promoted by the mechanical diffusion of the vapours

through the air with ventilating fans or chimney draughts; though under brisk ebullition, the force of the steam readily overcomes that mechanical resistance.

The quantities of water evaporated under different temperatures in like times, are proportional to the elasticities of the steam corresponding to these temperatures. A vessel of boiling water exposing a square foot of surface to the fire, evaporates about 725 grains in the minute; the elasticity of the vapour is equivalent to 30 inches of mercury. To find the quantity that would be evaporated from the same surface per minute at a heat of 82° F. — At this temperature the steam is combusted upon water is capable of supporting 1.34 inch of mercury; whence the rule of proportion is $30 : 725 :: 725 : 3093$; showing that about 31 grains of water would be evaporated in the minute. If the air contains already some aqueous vapour, as it commonly does, then the quantity of evaporation will be proportional to the difference between the elastic force of that vapour, and what rises from the water.

Suppose the air to be in the hygroscopic state denoted by 0.73 of an inch of mercury, then the above formula will become $30 : 1.28 = 0.93 :: 725 : 2141$; showing that not more than $2\frac{1}{2}$ grains would be evaporated per minute under these circumstances.

The elastic tension of the atmospheric vapour is readily ascertained by the old experiment of Le Roi, which consists in filling a glass cylinder (a narrow tumbler for example) with cold spring water, and noting its temperature at the instant it becomes so warm that dew ceases to be deposited upon it. This temperature is that which corresponds to the elastic tension of the atmospheric vapour. See Varroin, Table of

Whenever the elasticity of the vapour, corresponding to the temperature of the water, is greater than the atmospheric pressure, the evaporation will take place not only from its surface, but from every point in its interior; the liquid particles throughout the mass assuming the gaseous form, as rapidly as they are actuated by the caloric, which converts the hydrostatic equilibrium among them, to constitute the phenomena of ebullition. This turbulent vaporisation takes place at any temperature, even down to the freezing point, provided the pneumatic pressure be removed from the liquid by the air pump, or any other means. Ebullition always accelerates evaporation, as it serves to carry off the aqueous particles not simply from the surface, but from the whole body of the water.

The vapours exhaled from a liquid at any temperature contain more heat than the fluid from which they spring; and they cease to form whenever the supply of heat into the liquid is stopped. Any volume of water requires for its conversion into vapour about five times as much heat as is sufficient to heat it from the freezing to the boiling temperature. The heat, in the former case, seems to be absorbed, being unperceivable by the thermometer; for steam is no hotter than the boiling water from which it rises. It has been therefore called by Dr. Black, *latent heat*; in contradistinction to that perceived by the touch and measured by the thermometer, which is called *sensible heat*. The quantity of heat absorbed by one volume of water in its conversion into steam, is about 1000° Fahr.; it would be adequate to heat 1000 volumes of water, one degree of the *ann. scale*. Were the vessel charged with water or heated, opened, it would be instantaneously emptied by vaporisation, as the whole caloric, equivalent to its constitution as steam, is present. When upon the other hand, steam is condensed by contact with cold substances, so much heat is set free as is capable of heating about five times its weight of water from 32° to 212° F.

Equal weights of vapour of any temperature contain equal quantities of heat; for example, the vapour exhaled from one pound of water, at 77° F., absorbs during its formation, and will give out in its condensation, as much heat as the steam produced by one pound of water at 312° F. The first portion of vapour with a tension = 0.93 inches, occupies a space of 27.31 cubic feet; the second, with a tension of 0.93 inch, occupies a space of 890 cubic feet.* Suppose that these 890 volumes were to be compressed into 27.31 in a cylinder capable of condensing the heat, the temperature of the vapour would rise from 77° to 212° , in virtue of the condensation, as air behaves so but by compression in a syringe, as to *latent heat*. The latent heat of steam at 212° F. is $1180^{\circ} - 120 = 1060$; that of vapour, at 77° , is $1183 - 4 = 1179$; so that, in fact, the lower the temperature at which the vapour is exhaled, the greater is its latent heat, as Joseph Black and James Watt long ago proved by experiments upon distillation and the steam engine.

From the preceding researches it follows, that evaporation may be effected upon two different plans: —

1. Under the ordinary pressure of the atmosphere; and that either,

* One pound of water at 32° F. contains 27.31 cubic inches, or cubic feet of water; hence the volume of steam at 312° F. is the same one pound of water will form 27.31 cubic feet of such steam; and $0.93 : 80 = 27.31 : 890$ cubic feet.

a, by external application of heat to boilers, with *a*, an open fire; *b*, steam; *c*, hot liquid media.

n, by evaporation with air; *n*, at the ordinary temperature of the atmosphere; *l*, by currents of warm air.

3. Under progressively lower degrees of pressure than the atmospheric, down to evaporation in as perfect a vacuum as can be made.

It is generally affirmed, that a thick metallic boiler obstructs the passage of the heat through it so much more than a thin one, as to make a considerable difference in their relative powers of evaporating liquids. Dr. Ure states that he made a series of experiments upon this subject. Two cylindrical copper pans, of equal diameter, *a*, were provided; but the metal of the one was twelve times thicker than that of the other. Each being charged with an equal volume of water, and placed either upon the same hot plate of iron, or immersed, to a certain depth, in a hot solution of muriate of lime, he found that the ebullition was greatly more vigorous in the thick than in the thin vessel, which he ascribed to the conducting substance, up the sides, above the contact of the source of heat, being 12 times greater in the former case than in the latter.

If the bottom of a pan, and the portions of the sides, immersed in a hot fluid medium, solution of caustic potash or muriate of lime, for example, be corrugated, so as to contain a double exposure of metallic surface, that pan will evaporate exactly double the quantity of water, in a given time, which a like pan, with smooth bottom and sides, will do immersed equally deep in the same both. If the corrugations contain three times the quantity of metallic surface, the evaporation will be threefold in the above circumstances. Put if the pan, with the same corrugated bottom and sides, be set over a fire, or in an oblong flue, so that the current of flame may sweep along the corrugations, it will evaporate no more water from its interior than a smooth pan of like shape and dimensions placed alongside in the same flue, or over the same fire. This curious fact Dr. Ure states he has verified upon models constructed with many modifications. Among others, he caused a cylindrical pan, 10 inches diameter, and 6 inches deep, to be made of tin-plate, with a vertical plate soldered across its diameter; dividing it into two equal semi-cylindrical compartments. One of these was smooth at the bottom, the other corrugated; the former afforded as rapid an evaporation over the naked fire as the latter, but it was far outstripped by its neighbour when plunged into the heated liquid medium.

If a shallow pan of extensive surface be heated by a subjacent fire, by a liquid medium, or a series of steam pipes upon its bottom; it will give off less vapour in the same time when it is left open, than when partially covered. In the former case, the cool incumbent air precipitates by condensation a portion of the steam, and also opposes considerable mechanical resistance to the diffusion of the vaporous particles. In the latter case, as the steam issues with concentrated force and velocity from the contracted orifice, the air must offer less proportional resistance, upon the known hydrostatic principle of the pressure being as the areas of the respective bases of the communicating vessels.

In evaporating by surfaces heated with ordinary steam, it must be borne in mind that a surface of 10 square feet will evaporate fully one pound of water per minute, or $720 \times 10 = 7200$ gr., the same as over a naked fire; consequently the condensing surface must be equally extensive. Suppose that the vessel is to receive of water 2500 lbs., which corresponds to a boiler 6 feet long, 4 broad, and 2 deep, being 48 cubic feet by measure, and let there be laid over the bottom of this vessel 8 connected tubes, each 4 inches in diameter and 5 feet long, presenting therefore a surface of 48 feet square. If charged with steam, they will cause the evaporation of half a pound of water per minute. The boiler to supply the steam for this purpose must expose a surface of 48 square feet to the fire. It has been proved experimentally that 10 square feet surface of thin copper can condense 3 lbs. of steam per minute, with a difference of temperature of 90 degrees Fahr. In the above example, 48 square feet evaporate 1 lb. of water per minute; the temperature of the evaporating fluid being 212° F., consequently $3 : 1 :: 90 : 2^{\circ}$. During this evaporation the difference of the temperature is therefore -30° . Consequently the heat of the steam placed in connection with the interior of the boiler, to produce the calculated evaporation, should be, $212 + 30 = 242^{\circ}$, corresponding to an elastic force of 33.6 inches of mercury. Were the temperature of the steam only 224, the same boiler in the same time would produce a diminished quantity of steam, in the proportion of 12 to 30, or to produce the same quantity the boiler or tubular surface should be enlarged in the proportion of 30 to 12. In general, however, steam boilers employed for this mode of evaporation are of such capacity as to give an unfailing supply of steam.

We shall now illustrate by some peculiar forms of apparatus, different systems of evaporation. Fig. 729 explains the principles of evaporating in vacuum. A B repre-

sents a pan or kettle charged with the liquor to be evaporated. The somewhat wide orifice *c*, secured with a screw-plug, serves to admit the hand for the purpose of

720

cleaning it thoroughly out when the operation is finished; *h* is the pipe of communication with the steam boiler; *b* is a tube prolonged and then bent down with its end plunged into the liquor to be evaporated, contained in the charging back (not shown in the figure). *n* is a glass tube communicating with the vacuum pan at the top and bottom, to show by the height of the column the quantity of liquid within. The eduction evaporating pipe *c* is provided with a stop-cock to cut off the communication when required. *i* is a tube for the discharge of the air and the water from the steam-case or jacket; the refrigerator *r* is best formed of thin copper tubes about 1 inch in diameter, arranged zig-zag or spirally like the worm of a mill in a cylinder. The small air-tight condenser *r*, connected with the efflux pipe *f* of the refrigerator, is furnished below with a discharge cock *g*, and surrounded by a cooling case, for the collection of the water condensed by the refrigerator. In its upper part there is a tube *k*, also furnished with a cock, which communicates with the steam boiler, and through which the pan *A* is heated.

The operation of this apparatus is as follows. after opening the cocks *c*, *f*, *g*, and before admitting the cold water into the condenser *r*, the cock of the pipe *k* is opened, in order that by injecting steam it may expel the included air; after which the cocks *k* and *g* are to be shut. The water must now be introduced into the condenser, and the cock *b* opened, whereon the liquid to be evaporated rises from the charging back, through the tube *b*, and replenishes the vacuum pan to the proper height, as shown by the register glass tube *n*. Whenever the desired evaporation or concentration is effected, the cock *c* must be closed, the pipe *k* opened, so as to fill the pan with steam, and then the efflux cock *a* is opened to discharge the residuary liquor. By shutting the cocks *a* and *k*, and opening the cock *b*, the pan will charge itself afresh with liquor, and the operation will be begun anew, after *b* has been shut and *c* opened.

The contents of the cold water cistern *v*, may be drawn off during each operation. For this purpose, the cock *f* must first be shut, the cold water is to be then run out of the condenser *r*, and *k* and *g* are to be opened. The steam entering by *k* makes the water flow, but whenever the steam itself issues from the cock *g*, the orifice must be immediately shut, the cock *f* opened, and the cold water again introduced, whereupon the condensed water that had meanwhile collected in the under part of the refrigerator, flows off into the condenser vessel *r*. Since some air always enters with the liquor sucked into the pan, it must be removed at the time of drawing off the water from the two condensers, by driving steam through the apparatus. This necessity will be less urgent if the liquor be made to boil before being introduced into the vacuum pan.

Such an apparatus may be modified in size and arrangement to suit the peculiar

object in view, when it will be perfectly adapted for the concentration of extracts of every kind, as well as for solutions containing vegetable acids or alkalies. The interior vessel *A* should be made of tinned or plated copper. For an account of Howard's vacuum pan, made upon the same principle, see *STEAM*.

When a boiler is set over a fire, its bottom should not be placed too near the grate, lest it refrigerate the flame, and prevent that vivid combustion of the fuel essential to the maximum production of heat by its means. The evil influence of leaving too little room between the grate and the copper may be illustrated by a very simple experiment. If a small copper or porcelain capsule containing water be held over the flame of a candle a little way above its apex, the flame will suffer no abatement of brightness or size, but will continue to keep the water briskly boiling. If the capsule be now lowered into the middle of the flame, this will immediately lose its brightness, becoming dull and smoky, covering the bottom of the capsule with soot; and, owing to the imperfect combustion, though the water is now surrounded by the flame, its ebullition will cease.

Fig. 730 is a section of two evaporating coppers *as used*, so mounted as to favour the full combustion of the fuel. *A* is the hearth, in which wood or coal may be

burned. For coal, the grate should be set higher and be somewhat smaller. *a* is the door for feeding the fire; *d*, an arch of fire-bricks over the hearth; *c*, a grate through which the ashes fall into the pit beneath, capable of being closed in front to any extent by a sliding door *b*. *n* and *c* are two coppers encased in brickwork; *f* the flue. At the end of the hearth near *m*, where the fire plays first upon the copper, the sole is made somewhat lower and wider, to promote the spreading of the flame under the vessel. The second copper *c*, receives the benefit of the waste heat; it may be placed upon a higher level, so as to discharge its concentrated liquor by a stop-cock or siphon into the first.

Fig. 731 represents a pan for evaporating liquids, which are apt, during concentration, to let fall crystals or other sediment.

These would be injured either by the fire playing upon the bottom of the pan, or, by adhesion to it, they would allow the metal to get red hot, and in that state run every risk of being burnt or rent on the sudden intrusion of a little liquor through the incrustation. When large coppers have their bottoms planted in loam, so that the flame circulates in flues round their sides, they are said to be *cold set*.

A is a pear-shaped pan, charged with the liquid to be evaporated; it is furnished with a dome cover, in which there is an opening with a flange *f*, for attaching a tube, to conduct the steam wherever it may be required. *a* is the fire-place; *b*, the ash-pit. The conical part terminates below in the tube *g*, furnished with a stop-cock at its nozzle *h*. Through the tube *c d e*, furnished above and below with the stop-cocks *c* and *e'*, the liquid is run from the charging back or reservoir.

During the operation, the upper cock *e* is kept partially open, to replace the fluid as

it evaporates; but the under cock *c'* is shut. The flame from the fire-place plays round the kettle in the space *e*, and the smoke escapes downwards through the flue *f* into the chimney. The lower cylindrical part *g* remains thus comparatively cool, and collects the crystalline or other solid matter. After some time, the under stop-cock *c'*, upon the supply-pipe, is to be opened to admit some of the cold liquor into the cylindrical neck. That cock being again shut, the sediment settled, and the large stop-cock (a horizontal side valve would be preferable) *h* opened, the crystals are suffered to descend into the subjacent receiver; after which the stop-cock *h* is shut and the operation is continued. A construction upon this principle is well adapted for heating drying coppers, in which the sediment should not be disturbed, or exposed to the action of the fire. The fire-place should be built as for the brewing copper.

Fig. 732 represents an oblong evaporating pan, in which the flame, after heating along its bottom, turns up at its further end, plays back along its surface, and passes off into the chimney. A is a rectangular vessel, from 10 to 15 feet long, 4 to 6 feet broad, and 1 or $1\frac{1}{2}$ feet deep. The fire bricks, upon which the pan rests, are so arranged as to distribute the flame equally along its bottom.

Vaüenfrust in 1736 (*Annales de Chimie*) observed some remarkable facts connected with evaporation, which have since received some striking illustration from the experiments of M. Bontigny.

When water is thrown on a plate heated considerably above the boiling point of water, the liquid assumes a spheroidal form, and this condition has hence received the name of the "spheroidal state." This water rolls about like melted crystal without any signs of ebullition, and it is dissipated but very slowly. The explanation usually given is as follows:—"The cause of the phenomena appears to be this, water exhibits an attraction for the surface of almost all solids, and wets them; fluid mercury exhibits the opposite property, or repulsion for most surfaces. The attraction of water for surfaces brings it into the closest contact with them, and greatly promotes the communication of heat by a heated vessel to the water contained in it. But heat appears to develop a repulsive power in bodies, and it is probable that, above a peculiar temperature, the heated metal no longer possesses this attraction for water. The water not being attracted to the surface of the hot metal, and induced to spread over it, is not rapidly heated, and therefore boils off slowly."—*Graham*.

The explanation given by this excellent authority on all matters connected with physico-chemical science has been selected as representing fairly the prevailing view. It is not, however, quite satisfactory. The water is said to be at a sensible distance from the hot plate, and a layer of aqueous vapour of very high temperature is known to surround the water, and yet the spheroidal water does not acquire the boiling temperature. Here is evidence of some peculiar, and as yet unexplained condition, belonging, either to heat of a certain kind or degree, or to the molecules of the body under its influence.

Bontigny observed that water may pass into the spheroidal state at any temperature above 340° F., and remain in that state until the temperature falls to 288° F., when evaporation rapidly ensues. Ether and alcohol pass into the spheroidal state at 142° F. and 273° F. A thermometer being plunged in liquids while in the spheroidal state, indicated the following temperatures:—

Water	-	-	-	-	-	-	-	-	-	$265\frac{1}{2}^{\circ}$ F.
Absolute alcohol	-	-	-	-	-	-	-	-	-	167°
Ether	-	-	-	-	-	-	-	-	-	93°
Hydrochloric ether	-	-	-	-	-	-	-	-	-	50°
Sulphurous acid	-	-	-	-	-	-	-	-	-	13°

All these being some degrees below the boiling temperature of those fluids.

Bontigny has shown that the vapour escaping from water in the spheroidal state, although it has a very elevated temperature, does not possess the usual elasticity of steam; it does not exert an expansive power. But if the vessel from which the vapour is forming is allowed to cool, to a certain point, a degree of elasticity equal to the elevated temperature of the vapour is suddenly exerted. This is supposed by Bontigny to explain many steam boiler explosions.

Whenever evaporation takes place, it should be remembered, it produces cold—that is, it lowers the temperature of the body from which the evaporation is taking

place. Leslie, by the evaporation of ether in vacuo, froze mercury. Thilorier solidified carbonic acid by the intense cold produced by its own evaporation. Boulligny froze water in a red hot vessel, by the evaporation of sulphurous acid from the heated vessel in which the water is in the spheroidal state.

Further remarks on these points will be found under the heads respectively of COAL, STEAM BOILERS, VAPOUR.

EXOSMOSE and ENDOSMOSE. As some manufacturing processes involve the phenomena expressed by these two words, it appears necessary briefly to explain them.

When two liquids are separated by a porous sheet of animal membrane, unglazed earthenware, porous stone, or clay, these liquids gradually diffuse themselves, and supposing salt and water to be on one side of the division, and water only on the other, the saline solution passes in one direction, while the water, though with less intensity, passes in another.

Instead of the two words introduced by Dumas, Professor Graham proposes the use of the single term *Osmose* (from *osmos*, impulsion).

It was supposed that there was, at the same time, an impulsive force acting from without and another acting from within; that there was indeed a current flowing in, and another flowing out. It however appears to be proved that the *osmose* between water and saline solutions, consists not in the passage of two liquid currents, but in the passage of particles of the salt in one direction, and of pure water in the other. Professor Graham has observed, that common salt diffuses into water, through a thin membrane of ox-bladder deprived of its outer muscular coating, at the same rate as when no membrane is interposed. This force plays an important part in the functions of life, and it will be found to explain many of the phenomena associated with Dyeing, Tanning, &c.

EXOGENOUS. A botanical term, signifying growing by addition to the outer parts of the stem.

The stem varies in structure in four principal ways. It is either formed by successive additions to the outside of the wood, when it is called *exogenous*, or by successive additions to its centre, when it is called *endogenous*, or by the union of the bases of leaves, and the extension of the point of the axis, which is called *acrogenous*, or by simple elongation or dilatation where no leaves or buds exist, as among *Thallozoens*.—*Lindley*.

EXPANSION (Eng. and Fr.; *Ausdehnung*, Germ.) is the increase of bulk experienced by all bodies when heated, unless a change in molecular arrangement takes place, as in the case of clays in the potter's kiln.

Table I. exhibits the linear expansion of several solids by an increase of temperature from 32° to 212° Fahr.; Table II. exhibits the expansion in bulk of certain liquids.

If the density of water at 39° be called

at 212° it becomes - - - - 1.00000,

and its volume has increased to - - - - 0.9548,

at 77° it becomes - - - - 0.9973587,

and its volume has increased to only - - - - 1.00265,

which, though one fourth of the whole range of temperature, is only $\frac{1}{11}$ of the total expansion. Water at 60° F. has a specific gravity of - - - - 0.9991253,

and has increased in volume from 39° to 1.00000,

which is only about $\frac{1}{11}$ of the total expansion to 212°, with $\frac{1}{11}$ of the total range of temperature.

All gases expand the same quantity by the same increase of temperature, which from 32° to 212° Fahr. = 180° = 3, or 100 volumes become 1.375. For each degree of Fahr. the expansion is $\frac{1}{180}$.

When dry air is saturated with moisture, its bulk increases, and its specific gravity diminishes, because aqueous vapour is less dense than air, at like temperatures.

The following Table gives the multipliers to be employed for converting one volume of moist gas at the several temperatures, into a volume of dry gas.

Temperature.	Multiplier.	Temperature.	Multiplier.
50° F.	0.9870	64°	0.9799
54	0.9864	65	0.9793
55	0.9858	66	0.9786
56	0.9852	67	0.9779
57	0.9846	68	0.9772
58	0.9839	69	0.9765
59	0.9833	70	0.9758
60	0.9827	71	0.9751
61	0.9820	72	0.9743
62	0.9813	73	0.9735
63	0.9806		

Lavoisier and Laplace arrived, after an extensive series of experiments, at the two important conclusions following: —

1st. All solid bodies whatever, being gradually heated from the temperature of melting ice to that of boiling water, and then gradually cooled from the temperature of boiling water to that of melting ice, will be found to have exactly the same dimensions at the same temperature during the process of heating and cooling; the gradual diminution of bulk in cooling corresponding exactly with the gradual increase of bulk in heating.

2nd. Glass and metallic bodies gradually heated from the temperature of melting ice to that of boiling water, undergo degrees of expansion proportional to those of mercury at the same temperature; that is to say, between the limits just mentioned, the expansion of the solid corresponding to two degrees of the thermometer, is twice the expansion which corresponds to one degree, the expansion which corresponds to

three degrees is three times the expansion which corresponds to one degree, and so on; the quantity of expansion being multiplied in the same proportion as the number of degrees through which the thermometer has risen is multiplied. See HEAT, *Lardner's Cyclopedia*.

Experiments by Fresnel, Forbes, Powell, Trevelyan, and Tyndal have a tendency to prove that heat occasions a repulsion between the particles of matter at small distances. If a heated poker is laid slantingly on a block of lead at the ordinary temperature, it will commence to vibrate, first slowly, and will increase with such rapidity as to produce a musical note, which continues for some time, usually changing to an octave at the termination. These results would appear to prove a movement amongst the particles constituting the bar.

Some remarkable examples of expansion are furnished by the influence of sunshine on the Britannia Tubular Bridge.

The most interesting effect is that produced by the sun shining on one side of the tube, or on the top, while the opposite side and bottom remain shaded and comparatively cool; the heated portions of the tube expand, and thereby warp or bend the tube towards the heated side, the motion being sometimes as much as $2\frac{1}{2}$ inches vertically and $2\frac{1}{2}$ inches laterally.

While the tubes were supported on the temporary piers on the beach, these motions were easily observed. An arm carrying a pencil was fixed on the south side of the tube, at the centre, and a board was fixed on a post independent of the tube, and at right angles to it; the pencil was pressed against the board by a spring, and the rise and fall, and the lateral motions of the tube, were consequently placed on the board. In this way a very interesting diagram was taken daily. The lowest part of each figure is the starting point, or normal position of the tube, to which the pencil always accurately returns during the night. As soon as the sun rises in the morning it starts towards the right hand, rising obliquely, the top and one side of the tube being warmed, and the bottom and opposite side remaining unaffected. It continues thus till one o'clock, when the sun, having ceased to shine on the southern side, begins to warm the northern side, the top still retaining its high temperature, the tube thus acquires a nearly horizontal motion towards the left hand, the slight descent in the line indicating the diminished effects of the sun on the top as it gradually sinks. The greatest deflection to the left hand is not attained until sunset, after which the tube rapidly descends in a uniformly curved line to its resting point. In the summer time this point is hardly attained before the rising sun compels it to commence its journey anew. When the sun is frequently obscured by passing clouds, very curious diagrams are obtained. During the absence of the sun the tube begins to cool rapidly, and to return to its normal position, every passing cloud is thus beautifully recorded.

The middle of the centre arch of Southwark Iron Bridge rises one inch in the height of summer. When great lengths of iron pipe are laid down for the conveyance of steam or hot water, sliding joints are necessary to prevent destruction either of the apparatus or of the building in which it is placed.

The practical applications made of the expansion and contraction of metals by heat are many. The tire of a wheel is put on hot, and by its contraction on cooling, firmly binds the other parts of the wheel together; boiler plates are riveted with red-hot rivets; collars of metal are driven on while hot, and the like.

Millard drew together the walls of a building that had bulged, by screwing up bars of iron tight to the walls while they were hot, and a similar process was adopted in the Cathedral of Armagh.

Playfair and Joule (*Chemical Society's Memoirs*) have made a valuable series of researches on the expansion of bodies by heat, principally salts; these have not however any sufficient practical bearing to occupy our space.

EXPRESSED OILS. See OILS.

EXTRACTS. (*Extracts*, Fr; *Extracten*, Germ.) The older apothecaries used this term to designate the product of the evaporation of any vegetable juice or infusion, or decoction; whether the latter two were made with water, alcohol, or ether; whence arose the distinction of aqueous, alcoholic, and ethereal extracts.

Fourcroy made many researches upon these preparations, and supposed that they had all a common basis, which he called the *extractive principle*. But Chevreul and other chemists have since proved that this pretended principle is a heterogeneous and very variable compound. By the term *extract* therefore is now meant merely the whole of the soluble matters obtained from vegetables, reduced by careful evaporation to either a paste or solid consistence. The watery extracts, which are those most commonly made, are as various as the vegetables which yield them, some containing chiefly sugar or gum in great abundance, and are therefore innocent or inert; while others contain very energetic impregnations. The conduct of the evaporating heat is the capital point in the preparation of extracts. They should be always prepared if

possible, from the juice of the fresh plant, by subjecting its leaves or other succulent part, to the action of a powerful screw, or hydraulic press; and the evaporation should be effected by the warmth of a water bath, heated not beyond 100° or 120° F. Steam heat is now applied advantageously in some cases, where it is not likely to decompose any of the principles of the plant. But by far the best process for making extracts is *in vacuo*, upon the principles explained in the article *EVAPORATION*. It is much easier to fit up a proper apparatus of this kind, than most practical men imagine. The vacuum may either be made through the agency of steam, as there pointed out, or by means of an air-pump. One powerful air-pump may form and maintain a good vacuum under several receivers, placed upon the flat ground flanges of so many basins, each provided with a stop-cock at its side for exhaustion. The air-less basin containing the juice being set on the shelf of a water-bath, and exposed to a proper temperature, will furnish in a short time a large quantity of medicinal extract, possessing the properties of the plant unimpaired.

For exceedingly delicate purposes, the concentration may be performed in the cold, by placing saucers filled with the expressed juice over a basin containing sulphuric acid, putting a glass receiver over them, and exhausting its air.

The use of the air-pump for evaporating such chemical substances as are readily injured by heat, has been very common since Professor Leslie's discovery of the efficacy of the combined influence of rarefied air and an absorbing surface of sulphuric acid in evaporating water at low temperatures. It has been supposed that the virtues of narcotic plants in particular might be better obtained and preserved by evaporation *in vacuo* than otherwise, as the decomposing agency of heat and atmospheric oxygen would be thereby excluded. There is no doubt that extracts thus made from the expressed juices of fresh vegetables possess for some time at least, the green aspect and odour of the plants in far greater perfection than those usually made in the air, with the aid of artificial heat. Dr. Meurer, in the *Archiv. der Pharmacie* for April, 1843, has endeavoured to show that the colour and odour are of no use in determining the value of extracts of narcotics, that the albumen left unchanged in the extracts made *in vacuo*, tends to cause their spontaneous decomposition, and that the extracts made with the aid of alcohol, as is the practice in Germany, are more efficacious at first, and much less apt to be injured by keeping. M. Baldenius has, in the same number of the *Archiv*, detailed experiments to prove that the juices of recent plants mixed with alcohol, in the homœopathic fashion, are very liable to spontaneous decomposition. To the above expressed juice, the Germans add the alcoholic tincture of the residuary vegetable matter, and evaporating both together, prepare very powerful extracts.

F.

FACETTING. The process of cutting faces upon ornamental articles. Steel jewellery, such as beads, studs, buttons, — the ornaments on the hilts of dress-swords and similar objects, are ground on horizontal laps with fine emery. Facets on gold and silver are cut and polished on revolving wheels, after the same general method as that pursued by the lapidary for cutting facets on stones.

FACTORY. In the sense in which this term is introduced here, it is contracted from manufactory; meaning the place where workmen are employed in fabricating goods. To describe all the various factories, would be to describe all the different manufactures, or, at least, the arrangements of the machines by which the raw material is converted into marketable goods. There is but one kind of factory which will be described in this place. The arrangements of a cotton factory fairly represent all the arrangements for other branches of textile manufactures, and here this is specially described. Under *SILK*, *WOOL*, &c., will be found particulars of the machines used and their general arrangements in these factories respectively.

FACTORY, COTTON (*General Construction of*). There is no textile substance whose filaments are so susceptible of being spun into fine threads of uniform twist, strength, and diameter, as cotton wool. It derives this property from the smoothness, tenacity, flexibility, elasticity, peculiar length, and spiral form of the filaments; hence, when a few of them are pulled from a heap with the fingers and thumb, they lay hold of and draw out many others. Were they much longer they could not be so readily attenuated into a fine thread, and were they much shorter the thread would be deficient in cohesion. Hence the differences in the lengths of the cotton staple are of advantage in adapting them to different styles of spinning and different textures of cloth.

If we take a tuft of cotton wool in the left hand, and seizing the projecting fibres with the right, slowly draw them out, we shall perceive with what remarkable facility

they glide past each other, and yet retain their mutual connection, while they are extended and arranged in parallel lines, so as to form a little ribband susceptible of considerable elongation. The demonstration of the ductility, as to speak, of cotton wool, succeeds still better upon the carded fleece in which the filaments have acquired a certain parallelism; for in this case the tiny ribband, in being drawn out by the fingers to a moderate length, may at the same time receive a gentle twist to preserve its cohesion till it becomes a fine thread.

Hence we may imagine the steps to be taken or the mechanical processes to be pursued in cotton spinning. After freeing the wool of the plant from all foreign substances of a lighter or a heavier nature, the next thing is to arrange the filaments in lines as parallel as possible, then to extend them into regular ribbands, to elongate these ribbands by many successive draughts, doubling, quadrupling, or even octupling them meanwhile, so as to give them perfect equality of size, consistence and texture, and at the same time to complete the parallelism of the fibres by undoing the natural convolutions they possess in the pod. When the rectilinear extension has been thus carried to the fineness required by the spinner, or to that compatible with the staple, a slight degree of torsion must accompany the further attenuation; which torsion may be either momentary, as in the tube roving machine, or permanent, as in the bobbin and fly frame. Finally, the now greatly attenuated soft thread, called a *fine roving*, is drawn out and twisted into finished cotton yarn, either by continuous indefinite gradations of drawing and twisting, as in the throstle, or by successive stretches and torsions of considerable lengths at a time, as in the mule.

Mechanical spinning consists in the suitable execution of these different processes by a series of different machines. After the carding operation, these are made to act simultaneously upon a multitude of ribbands and spangy cords or threads by a multi-tude of mechanical hands and fingers. However simple and natural the above described course of manufacture may appear to be, innumerable difficulties stood for ages in the way of its accomplishment; and so formidable were they as to render their entire removal of late years in the cotton factories of England one of the greatest and most honourable achievements of human genius.

The various operations may be thus classified for fine spinning:—

1. The *mixing* and opening up or loosening the flocks of cotton wool, as imported in the bags, so as to separate at once the coarser and heavier impurities as well as those of a lighter and finer kind.

2. The *willocking, scutching* or *blowing*, and *lapping*, to remove seeds and dirt, and prepare the material in the form of a continuous lap or sheet for the next operation of

3. The *carding*, which is intended to disentangle every tuft or knot, to remove every remaining impurity which might have eluded the previous operation, and finally to prepare for arranging the fibres in parallel lines, by laying the cotton first in a fleece web, and then in a ribband form.

4. The *doubling* and *drawing out* of the card-ends or ribbands, in order to complete the parallelism of the filaments, and to equalise their quality and texture.

5. The *roving* operation, whereby the *drawings* made in the preceding process are greatly attenuated, with no more twist than is indispensable to preserve the uniform continuity of the spangy cords.

6. The *fine roving* and *stretching* come next; the former operation being effected by the fine bobbin and fly frame, the latter by the stretcher mule.

7. The *spinning* operation finishes the extension and twist of the yarn, and is done either in a continuous manner by the throstle, or discontinuously by the mule; in the former, the yarn is progressively drawn, twisted, and wound upon the bobbins; in the latter, it is drawn out and twisted in lengths of from 36 to 67 inches, which are then wound all at once upon the spindles.

8. The eighth operation is the *winding, doubling*, and *singeing* of the yarns, to fit them for the maulin, the stocking, or the bobbin net lace manufacture.

9. The *packing press*, for making up the yarn into bundles for the market, concludes this series.

Note.—Yarns spun for weaving into cloth, as named in the 8th operation, after being wound, are at once warped, and after being sized, or dressed, are ready for the loom.

10. To the above may be added the operations of the dressing machines, for fine warps; the tape leg machine, for medium counts of warps, say 24s. to 50s., and sizing troughs for warps of coarser counts.

11. The power looms.

12. The *planting*, or *folding* and *measuring* machines.

13. The press for compressing the bundles of cloth ready for delivery.

The site of the factory ought to be carefully selected in reference to the health of the

operatives, the cheapness of provisions, the facilities of transport for the raw materials, and the convenience of a market for the manufactured articles. An abundant supply of labour, as well as fuel and water for mechanical power, ought to be primary considerations in setting down a factory. It should therefore be placed, if possible, in a populous village, near a river or canal, but in a situation free from malarial influences, and with such a slope to the vaster stream as may ensure the ready discharge of all liquid impurities. These circumstances happily conspire in the districts of Stockport, Hyde, Stalybridge, Dokenfield, Bury, Blackburn, &c., and have eminently favoured the rapid extension of the cotton manufactures for which these places are pre-eminent.

To better illustrate the above-named requisites for cotton spinning and manufacturing, we proceed to a description of a mill at Stockport, Lancashire, containing the large number of 61,400 throstle and mule spindles, and 1320 power looms.

Mr. R. McClure's Cotton Factory.—The mill consists of a main body with two lateral wings, projecting forwards, the latter being appropriated to store-rooms, a counting-house, rooms for winding the yarn on bobbins, and other miscellaneous purposes. The building has six floors besides the attic story. The ground-plan comprehends a plot of ground 280 feet long by 200 broad, exclusive of the boiler sheds.

The right-hand end, *A* (*fig. 733*) of the principal building, is separated from the main body by a strong wall, and serves in the three lower stories for accommodating two forty-horse steam engines, which are supplied with steam from a range of boilers contained in a low shed exterior to the mill.

The three upper stories over the steam engine gallery are used for unpacking, sorting, picking, cleaning, willoving, and lapping the cotton wool. Here are the willow, the blowing, and the lap machines, in a descending order, so that the lap machine occupies the lowest of the three floors, being thus most judiciously placed on the same level with the preparation room of the building. On the fourth main floor of the factory there are, in the first place, a line of carding engines arranged, near and parallel to the windows, as shown at *n n*, in the ground plan (*fig. 733*), and, in the second place, two rows of drawing frames, and two of bobbin and fly frames, in alternate lines, parallel to each other, as indicated by *v, c, n, c*, for the drawing frames, and *e, z, v, z*, for the bobbin and fly frames in the ground plan. The latter machines are close to the centre of the apartment.

The two stories next under the preparation room are occupied with throstle frames, distributed as shown at *r r*, in the ground plan. They stand in pairs alongside of each other, whereby two may be tended by one person. These principal rooms are 280 feet long, and nearly 50 feet wide. The two stories, over the preparation room, viz., the fifth and sixth floors from the ground, are appropriated to the mule jennies, which are placed in pairs fronting each other, so that each pair may be worked by one man. Their mode of distribution is shown at *o o*, in the ground plan. The last single mule is seen standing against the end wall, with its head-stock projecting in the middle.

The ground floor of the main building, as well as the extensive shed abutting behind it, marked by *s, u, u*, in the plan, is devoted to the power looms, the mode of placing which is plainly seen at *u, u, u*.

The attic story accommodates the winding frames, and warping mills, and the warp sizing machines, subservient to power weaving.

Some extra mules (self-actors), are placed in the wings.

We shall briefly sum up the references in the ground plan as follows:—

A, the ground apartment for the steam engines.

n, the distribution of the carding engines, the moving shaft or axis running in a straight line through them, with its pulleys, for receiving the driving bands.

c, c, the drawing frames.

n n, the jack, or coarse bobbin and fly frames.

n z, the fine roving, or bobbin and fly frames.

r, the arrangement of the throstle frames, standing in pairs athwart the gallery, in the 2nd and 3rd flats.

o, the mules are here represented by their roller beams, and the outlines of their head stocks, as placed in the 5th and 6th stories.

u, the looms, with their driving pulleys projecting from the ends of their main axes. Sometimes the looms are placed in parallel straight lines, with the rigger pulleys of the one alternately projected more than the other, to permit the free play of the driving-belts; sometimes the looms are placed, as generally in this engraving, alternately to the right and left by a small space, when the pulleys may all project equally. The former plan is the one adopted in Mr. Orrell's mill.

s, represents the cast-iron girders which support the floors of this fire-proof building.

733

784

K, k, are closets placed in each floor, in the recesses of a kind of pilasters built against the outside of the edifice. These hollow shafts are joined at top by horizontal pipes, which all terminate in a chest connected with the suction axes of a fan, whereby a constant draught of air circulates up the shafts, ventilates the apartments, and prevents the reflux of offensive effluvia from the water-closets, however careless the work-people may be. The closets towards the one end of the building are destined for the men; towards the other for the women.

L, l, are the staircases, of a horse-shoe form, the interior space or shaft in the middle being used for the teagle or hoist. In the posterior part of the shaft a niche or groove is left for the counter-weight to slide in, out of the way of the ascending and descending platform.

N, n, are the two porters' lodges, connected to the corner of each wing by a handsome iron balustrade. They are joined by an iron gate.

It will be observed that the back loom-shed has only one story, as shown in section (fig. 735). In the ground plan of the shed, *n* represents the roofing, of wood-work. The rafters of the floors rest at their ends upon an iron plate, or shoe with edges (as it is called), for the girders to bear upon.

Two steam engines, of fully 100 horse-power each, and two of 50 horse-power each, operate by cranks, which stand at right angles upon the shaft marked *a* both in the plan and section. In the centre, between the bearings, is a large cog-wheel, driving a smaller one upon the shaft marked *b* in both figures, to which the fly-wheel belongs. That prime motion wheel is magnificent, and possesses a strength equal to a strain of 300 horses. From this shaft motion is given to the main or upright shaft *d*, in the section, by two bevel wheels, visible at the side and on the top of the great block of stone, about 5 tons weight (fig. 735), which gives a solid basis to the whole moving apparatus.

The velocity of the piston in these steam engines is 240 ft. per minute.

The first shaft makes 443 revolutions per minute; the main upright shaft 58.84 per minute. The steam engine makes 16 strokes per minute; and the length of their stroke is 7 ft. 6 in.

As the one engine exerts its maximum force when the other has no force at all, and as the one increases as the other diminishes in the course of each pair of strokes, the two thus co-operate in imparting an equal impulsion to the great gearing and shafts, which, being truly made, highly polished, and placed in smooth bearings of hard brass, revolve most silently and without those vibrations which so regularly recurred in the old factories, and proved so detrimental to the accurate performance of delicate spinning frames.

The steam for these four engines is supplied by four high pressure horizontal engines, made by B. Goodfellow of Hyde, the exhausted steam from which has still power enough to drive the low pressure condensing engines. By an ingenious arrangement the condensing water from these engines, while on its return to the river is made to turn an 8 horse water-wheel.

A 12-horse auxiliary engine for driving the warping mills, sizing and drying frames, and mechanic's shop at night (in the event of breakages to the machinery) completes the power of this great mill, equalling over 1000 indicated horse-power, all the steam being supplied by 3 boilers carrying 70 lbs. pressure.

Note.—Prior to the application of the principle of compounding or uniting high and low-pressure engines, the above-named four low pressure engines required nine boilers, carrying 14 lbs. pressure, to supply them with sufficient steam; now, as we have shown, boilers of smaller dimensions, carrying 70 lbs. pressure, supply a sufficient quantity of steam, for increased power, at a reduction of fifty per cent. on the consumption of coal.

The power for driving the machinery is conveyed from the engine rooms by shafting in the usual manner.

To the horizontal ramifications from the upright shaft any desired velocity of rotation may be given by duly proportioning the diameters of the bevelled wheels of communication between them; thus, if the wheel on the end of the horizontal shaft have one-half or one-third the diameter of the other, it will give it a double or a triple speed.

In the lowest floor, the second bevel wheel above the stone block drives the horizontal shaft *e*, seen in the ground plan; and thereby the horizontal shaft *f*, at right angles to the former, which runs throughout the length of the building, as the other did through its breadth, backwards. The shaft *f* lies alongside of the back window wall, near the ceiling; and from it the transverse slender shafts proceed to the right and left in the main building, and to the shed behind it, each of them serving to drive two lines of looms. These slender or branch shafts are mounted with pulleys, each of which drives four looms by four separate bands.

735

In the second and third floors, where the throistles are placed, the shaft *d* is even in the section to drive the following shafts:—

Upon the main upright shaft *d* (fig. 735), there are in each of these stories two horizontal bevel wheels, with their faces fronting each other (shown plainly over *d d*), by which are moved two smaller vertical bevel wheels, on whose respective axes are two parallel shafts, one over each other, *g g*, which traverse the whole length of the building. These two shafts move therefore with equal velocities, and in opposite directions. They run along the middle space of each apartment; and wherever they pass the rectangular line of two throistle frames (as shown at *r* in the ground plan) they are each provided with a pulley; while the steam pulleys on the axes of two contiguous throistles in one line are placed as far apart as the two diameters of the said shaft-pulleys. An endless strap goes from the pulley of the uppermost horizontal shaft round the steam or driving-pulley of one throistle frame; then up over the pulley *g*, the second or lower shaft, *g*; next up over the steam pulley of a second throistle; and, lastly, up to the pulley of the top shaft, *g*. See *g g* in the throistle floors of the cross section.

In the preparation room, three horizontal shafts are led pretty close to the ceiling through the whole length of the building. The middle one, *h* (see the plan, fig. 734), is driven immediately by bevel wheels from the main upright shaft *d* (fig. 734). The two side ones *i, i*, which run near the window walls, are driven by two horizontal shafts, which lead to these side shafts. The latter are mounted with pulleys, in correspondence with the steam pulleys of the two lines of carding engines, as seen between the cards in the plan. The middle shaft *h*, drives the two lines of bobbin and fly frames, *k, k, m, n* (see cross section), and short shafts *i, i*, seen in the cross section of this floor, moved from the middle shaft *h*, turning the gallows fixed to the ceiling, over the drawing and jack frames, give motion to the latter two sets of machines. See *c n* in the cross section.

To drive the mules in the uppermost story, a horizontal shaft *h* (see longitudinal and cross sections, as well as ground plan) runs through the middle line of the building, and receives motion from bevel wheels placed on the main upright shaft, *d*, immediately beneath the ceiling of the uppermost story. From that horizontal shaft, *h*, at every second mule, a slender upright shaft, *l*, passing through both stories, is driven (see both sections). Upon these upright branch shafts are pulleys in each story, one of which serves for two mules, standing back to back against each other. To the single mules at the ends of the rooms, the motions are given by still slenderer upright shafts, which stand upon the head stocks, and drive them by wheel-work, the steps (top bearings) of the shafts being fixed to brackets in the ceiling.

In the attic, a horizontal shaft *m m*, runs lengthwise near the middle of the roof, and is driven by wheel-work from the upright shaft. This shaft, *m*, gives motion to the waring mills and dressing machines.

This cotton mill having been erected according to plans devised and executed by that very eminent engineer, Mr. Fairbairn, of Manchester, may be justly reckoned a model of factory architecture. It is mounted with 1320 power-looms, of which each 100 require steam power equivalent to 25 horses to impel them, inclusive of the preparation and spinning operations competent to supply the looms with yarn.

Ten looms, with the requisite dressing, without spinning, are considered to be equivalent to 1 horse power in a steam engine. Steam power equivalent to 1 horse will drive—

500 mule spindles,

300 self-actor spindles,

150 throistle spindles of the common construction; in which estimate the requisite preparation processes are included.

In Mr. St-Clure's mill there are in the throistle-frame

floors	-	-	-	-	-	-	-	27,200	spindles
And in the mule floors	-	-	-	-	-	-	-	34,200	"

Total yarn spindles - 61,400

To which add, power-looms 1320, producing the product of the spindles, in the shape of 300,000 yards of cloth in every week of 60 hours.

One of the most compact and best regulated modern factories, on the small scale, which we visited in Lancashire, consisted of the following system of machines:—

1 willow, 1 blowing machine, 1 lap machine, capable, together, of cleansing and lapping 9000 pounds of cotton per week, if required.

21 cards, blakers, and finishers, which carded 5000 lbs. of cotton every week of 60 hours' work, being about 240 lbs. per card.

3 drawing-frames, of 3 heads each.

- 3 coarse bobbin and fly frames.
- 7 fine bobbin and fly frames. No stretcher mule.
- 12 self-actor mules, of Sharp and Roberia's construction, of 401 spindles each = 4812 male spindles.
- 10 throstle frames, of 236 spindles each = 2360 spindles.
- 7 dressing machines.
- 336 power-loom.
- 2 warping mills.
- 300 winding spindles for winding the warp.

The rovings have 4 hanks in the pound, and are spun into yarn No. 38 on the throstle, as well as the mule.

One bobbin of the roving (compressed) lasts 5 days on the self-actors, and 6 days on the throstle.

According to the estimate of Peel and Williams, of Manchester, 66 horses power of a steam engine are equivalent to 396 power-loom, including 16 dressing machines; the cloth being 36 inches wide upon the average, and the yarn varying in fineness from 18's to 40's, the mean being 26's. Here, the spinning and preparation not being included, the allowance of power will appear to be high. The estimate given above assigns 10 looms, with the requisite dressing, to 1 horse; but the latter assigns no more than 6.

For the following experimental results, carefully made with an improved steam engine indicator, upon the principle of Mr. Watt's construction, we are indebted to Mr. Bennet, an engineer in Manchester. His mode of proceeding was to determine, first of all, the power exerted by the factory steam engine when all the machines of the various floors were in action; then to detach, or throw out of gear, each system of machines, and to note the diminution of force now exercised. Finally, when all the machines were disengaged, he determined the power requisite to move the engine itself as well as the great gearing-wheels and shafts of the factory.

He found at the factory of J. A. Beaver, Esq., in Manchester, that 500 calico looms (without dressing) took the power of 33 horses, which assigns 15 looms to 1 horse power.

At Messrs. Birley's factory, in Manchester, he found that 1080 spindles in 3 self-actor mules took 2.52 horses, being 417 spindles for 1 horse power; that 3960 spindles in 11 self-actors took 5.33 horses, being 475 spindles per horse power; 1,080 spindles in 3 self-actors took 2 horses, being 540 spindles per horse.

At Messrs. Clarke and Sons, in Manchester, that 585 looms in weaving fastians of various breadths took 54 horses power, exclusive of dressing machines, being 11 looms to 1 horse.

At J. A. Beaver's, on another occasion, he found that 1200 spindles, of Danforth's construction, took 21 horses, being 57 spindles per horse power; and that in a second trial the power of 23 horses was required for the same effect, being 52 Danforth's spindles per horse power.

An excellent engine of Messrs. Boulton and Watt, being tried by the indicator, afforded the following results in a factory:—

A 60 horse boat-engine (made as for a steam boat) took	
14½ horses power to drive the engine with the shafts	14.5
3½ blowing machines, with their 3 fans	21.25
10 dressing machines	10.25
12 self-actor mules of 360 spindles each (720 spindles per horse power)	6.00
6 Danforth's throstle frames, containing 370 spindles (36 in each), being 93 spindles to 1 horse power	6.20

At Bollington, in a worsted mill, he found that 106½ spindles, including preparation, took 1 horse power upon throstles. N. B. There is no carding in the long wool or worsted manufacture for merino.

At Bradford, in Yorkshire, he found that a 40 horse power boat-engine, of Boulton and Watt's, drove 503 calico looms, 6 dressing machines (equivalent to dress warp for 180 of the said looms), and 1 mechanics' workshop, which took 2 horses power. Other engineers estimate 300 common throstle spindles, by themselves, to be equivalent to the power of 1 horse.

The shafts which drive the cards revolve about 120 times per minute, with a driving pulley of from 15 to 17 inches in diameter.

The shafts of the drawing and the bobbin and fly frames revolve from 160 to 200 times per minute, with pulleys from 18 to 24 inches in diameter.

The shafts of throstle frames in general turn at the rate of from 220 to 240 times per

minute, with driving pulleys 18 inches in diameter, when they are spinning yarn of from No. 35 to 40. The shafts of mules revolve about 130 times per minute, with pulley 16 inches in diameter.

The shafts of power looms revolve from 110 to 120 times per minute, with pulleys 15 inches in diameter.

The shafts of dressing machines revolve 60 times per minute, with pulleys 14 inches in diameter.

Before quitting the generalities of the cotton manufacture we may state the following facts communicated also by Mr. Bennet:—

A waggon-shaped boiler, well set, will evaporate 12 cubic ft. of water with 1 cwt. of coals; and a steam-boiler with winding flues will evaporate 17 cubic ft. with the same weight of fuel. $7\frac{1}{2}$ lbs. of coals of the former boiler are equivalent to 1 horse power exerted for an hour, estimating that a horse can raise 33,000 lbs. 1 foot high in a minute.

The first cotton mill upon the fire-proof plan was erected by the Messrs. Strutt, at Belper, in the year 1797; that of Messrs. Phillips and Lee, at Manchester, in 1801; that of H. Houldsworth, Esq., of Glasgow, in 1802; and that of James Kennedy, at Manchester, in 1805; since which time many good factories have been built fire-proof, like Mr. McClure's.

The heating of the apartments of cotton factories is effected by a due distribution of cast-iron pipes, of about 7 or 8 inches diameter, which are usually suspended a little way below the ceilings, traverse the rooms in their whole length, and are filled with steam from boilers exterior to the building. It has been ascertained that one cubic foot of boiler will heat fully more than 3,000 cubic ft. of space in a cotton mill, and maintain it at the temperature of about 75° Fahr. If we reckon 25 cubic ft. contents of water in a waggon-shaped steam boiler as equivalent to 1 horse power, such a boiler would be capable of warming 50,000 cubic ft. of space; and therefore a 10 horse steam boiler will be able to heat 500,000 cubic ft. of air from the average temperature, 50°, of our climate, up to 75°, or perhaps even 80° Fahr.

It has been also ascertained that in a well-built cotton mill, one superficial foot of exterior surface of cast-iron steam pipe will warm 200 cubic ft. of air. In common cases for heating churches and public rooms, we believe that one-half of the above heating surface will be found adequate to produce a sufficiently genial temperature in the air. The temperature of the steam is supposed to be the same with that in Mr. Watt's low-pressure engines, only a few degrees above 212°—the boiling point of water.

The pipes must be freely along, and left at liberty to expand and contract under the changes of temperature, having one end at least connected with a flexible pipe of copper or wrought iron, of a swan-neck shape. Through this pipe the water of condensation is allowed to run off. The pipes should not be laid in a horizontal direction, but have a sufficient slope to discharge the water. The pipes are cast from half an inch to three-quarters thick in the metal. In practice the expansion of steam pipes of cast-iron may be taken at about one-tenth of an inch in a length of 10 feet, when they are heated from a little above the freezing to the boiling point of water. The upper surface of a horizontal steam pipe is apt to become hotter than the bottom, of the water be allowed to stagnate in it; the difference being occasionally so great, as to cause a pipe 60 feet long to be bent up two inches in the middle.

In arranging the steam pipes provision ought to be made not only for the discharge of the water of condensation, as above stated, but for the ready escape of the air; otherwise the steam will not enter freely. Even after the pipes are filled with steam, a little of it should be allowed to escape at some extreme orifice, to prevent the re-accumulation of air discharged from the water of the steam boiler. In consequence of water being left in the pipes serious accidents may happen; for the next time the steam is admitted into them, the regularity of heating and expansion is impeded, some part of the pipe may crack, or a violent explosion may take place, and the joints may be racked to a very considerable distance, every way, from the place of rupture, by the alternate expansions and condensations. The pipes should therefore be laid, so as to have the least possible declivity, in the direction of the motion of the steam.

Formerly, when drying rooms in calico printing works were heated by iron stoves, or cockles, their inmates were very unhealthy, and became emaciated; since they have been heated by steam pipes the health of the people has become remarkably good, and their appearance frequently blooming.

FACTORY is also a place where factors meet to dispose of goods, as Tea factories, &c. &c.

FAHLERZ. Grey copper-ore, called also *Punabaz*, from the many oxides it contains, and *Tetrahedrita* from its form.

The analysis of a crystallised specimen from Huel Prosper, in Cornwall, gave

Copper	-	-	30.18	Antimony	-	-	23.66
Silver	-	-	traces	Arsenic	-	-	4.40
Iron	-	-	6.99	Sulphur	-	-	25.04
Zinc	-	-	traces				

Specimens from Baden and Freiberg have been found to contain as much as from 18 to 31 per cent. of silver. The following analysis by M. Rose, of grey copper ore, or Fahlerz, will show the variation in composition of this interesting mineral. —

	Galena.	Antimony.	Copper.
1. St. Marie Auxillines, in Alsace	26.83	15.46	40.60
2. Geroldorf, Freiburg	26.33	16.51	38.63
3. Kapnik, Hungary	25.77	27.94	37.88
4. Dillenbourg, in Nassau	25.00	26.27	33.42
5. Mine Zaida, at Clausthal	24.73	28.24	31.48
6. Mine Wenzel, near Wolfenach, Baden	23.52	26.63	25.27
7. Mine Kabacht, near Freiburg	21.17	24.63	44.81

Besides Arsenic, Iron, Zinc, and Silver.

FAINTS is the name of the impure spirit which comes over first and last in the distillation of whiskey; the former being called the *strong*, and the latter, which is much more abundant, the *weak faints*. This crude spirit is much impregnated with smelly essential oil (fusel oil), it is therefore very unwholesome, and must be purified by rectification.

FALSE TOPAZ. A light yellow pellucid variety of quartz crystal. It may be distinguished from yellow topaz, for which when cut it is frequently substituted, by its difference of crystalline form, the absence of cleavage, inferior hardness, and lower specific gravity. Found in the Brazil, &c.

FAN (*Eretnak*, Fr.; *Fächer*, Germ.) is usually a semi-circular piece of silk or paper, pasted double, enclosing slender slips of wood, ivory, tortoise-shell, whale-bone, &c., arranged like the tail of a peacock in a radiating form, and susceptible of being folded together, and expanded at pleasure. This well-known hand ornament is used by ladies to cool their faces by agitating the air. Fans made of feathers, like the wing of a bird, have been employed from time immemorial by the natives of tropical countries.

FAN is also the name of the apparatus for winnowing corn, for drying the fires of furnaces, and for purposes of ventilation. For an account of the powerful blowing and ventilating fan machines, see **FURNACE** and **VENTILATOR**.

FANG, a mining term. A niche cut in the side of an adit or shaft, to serve as an air course. Sometimes the term a *fang* is applied to a mass of wood pupa.

PARINA (*Farine*, Fr.; *Mehl*, Germ.) is the flour of any species of corn, or starchy root, such as potato, arrow-root, &c. See **BARAD** and **STARCH**.

FATS (*Grasses*, Fr.; *Fette*, Germ.) occur in a great number of the animal tissues, being abundant under the skin in what is called the cellular membrane, round the kidneys, in the folds of the omentum, at the base of the heart, in the mesenterium, the mesentery web, as well as upon the surface of the intestines, and among many of the muscles. Fats vary in consistence, colour, and smell, according to the animals from which they are obtained; thus, they are generally fluid in the cetaceous tribes, soft and rank-flavoured in the carnivorous, solid and nearly scentless in the ruminants, usually white and copious in well fed young animals; yellowish and more scanty in the old. Their consistence varies also according to the organ of their production; being firmer under the skin and in the neighbourhood of the kidneys than among the movable viscera. Fat forms about one-twentieth of the weight of a healthy animal. But as taken out by the butcher it is not pure; for being of a vascular structure it is always enclosed in membranes, mixed with blood, blood-vessels, lymphatics, &c. These foreign matters must first be separated in some measure mechanically, after the fat is minced small, and then more completely by melting it with hot water, passing it through a sieve, and letting the whole cool very slowly. By this means a cake of cleansed fat will be obtained.

Bracegirdle and Raspall have shown that solid animal fats are composed of very small microscopic, partly polygonal, partly reniform particles, which are collected together by very thin membranes. These may be ruptured by mechanical means, then separated by triturating the fresh fats with cold water, and passing the mixture through a sieve. The particles float in the water, but eventually collect in a white

granular crystalline appearance, like starch. Each of them consists of a vesicular integument, of the nature of stearine, and an interior fluid like oleine, which afterwards exudes. The granules float in the water, but subside in spirits of wine. When digested in strong alcohol, the liquid part dissolves, but the solid remains. These particles differ in shape and size, as obtained from different animals; those of the calf, ox, sheep, are polygonal, and from $\frac{1}{16}$ to $\frac{1}{32}$ of an inch in diameter; those of the sow are kidney-shaped, and from $\frac{1}{16}$ to $\frac{1}{32}$; those of man are polygonal, and from $\frac{1}{16}$ to $\frac{1}{32}$; those of insects are spherical, and at most $\frac{1}{16}$ of an inch.

Fats all melt at a temperature much under 212° F. When strongly heated with contact of air, they diffuse white pungent fumes, then blacken, and take fire. When subjected to distillation they afford a changed fluid oil, carburetted hydrogen, and the other products of oily bodies. Exposed for a certain time to the atmosphere, they become rancid, and generate the same fat acid as they do by saponification. In their fresh state they are all composed principally of stearine, margarine, and oleine, with a little colouring and odorous matter; and in some species, hircine, from the goat; phocenine, from the dolphin; and butyrine from butter. By subjecting them to a great degree of cold, and compressing them between the folds of blotting paper, a residuum is obtained, consisting chiefly of stearine and margarine; the latter of which may be dissolved out by oil of turpentine.

Beef and Mutton Suet.—When fresh, this is an insipid, nearly inodorous fat, of a firm consistence, almost insoluble in alcohol, entirely so, if taken from the kidneys and mesenteric web of the ox, the sheep, the goat, and the stag. It varies in its whiteness, consistence, and combustibility, with the species and health of the animals. They may all be purified in the manner above described. Strong sulphuric acid develops readily the acid fats by stirring it through melted suet. Alkalies, by saponification, give rise to one of the three acids,—the stearic, margarine, or oleic. Beef suet consists of stearine, margarine, and oleine; mutton and goat suet contain a little hircine. The specific gravity of the tallow of which common candles are made is, by Berzeliuss's experiments, 0.936. The melting point of suet is from 98° to 104° F. The proportion of solid and fluid fat in it is somewhat variable, but the former is in much larger proportion. Mutton suet is soluble in 44 parts of boiling alcohol, of 0.820; beef suet in 44 parts. Marrow fat consists of 76 of stearine, and 24 of oleine; it melts at 115° F.

Hog's lard is soft, fusible at 81° F., convertible, by an alkaline solution, into a stearate, margarate, oleate, and glycerine. Its sp. grav. is 0.938, at 50° F. It consists of 62 of oleine, and 38 of stearine, in 100 parts.

Goose-fat consists of 68 oleine and 32 stearine.

Butter, in summer consists of 60 of oleine and 40 of stearine; in winter, of 35 of oleine, and 65 of stearine; the former substance being yellow and the other white. It differs, however, as produced from the milk of different cows, and also according to their pasture.

The ultimate constituents of stearine, according to Chevreul, are, 79 carbon; 11.7 hydrogen; and 9.3 oxygen in 100 parts.

See MARGARINE, OLEINE, SOAP, STEARINE.

The following statement is given on the authority of Braconnot:—

	Oleine.	Stearine.
Fresh butter in summer	60	40
— in winter	37	63
Hog's lard	62	38
Ox marrow	24	76
Goose fat	68	32
Duck fat	72	28
Ox tallow	25	75
Mutton suet	26	74

Dr. Robert Dumas Thomson has given the following list of animal fats and their melting points:—

Badger fat	86°	Duck's fat	77°
Beef tallow	98½	Dog	79½
Calf	136.8	Fox	129
Camel	131	Hare	117½
Cochineal fat	104	Hog's lard	80.5
Cow's butter	79.7	Horse grease	140

Human fat	- - -	77°	Stearine (duck)	- - -	106°
Phœasant	- - -	109	Otine	- - -	130
Turkey	- - -	113	Chlorstearine	- - -	278
Stearine (human)	- - -	120	Cantharides fat	- - -	93½
" (sheep)	- - -	109	Margarine (butter)	- - -	103
" (oxen)	- - -	111	Palmitine	- - -	113
" (hog)	- - -	109			

M. Dumas says that butter contains no stearine. The purification and decoration of fats has been the object of many patents. One of the best is to mix two per cent. of strong sulphuric acid with a quantity of water, in which the tallow is heated for some time with much stirring; to allow the materials to cool, to take off the supernatant fat, and to re-melt it with abundance of hot water. More tallow will thus be obtained, and that considerably whiter and harder than is usually procured by the melters.

Mr. Fre states that he has found that chlorine and chloride of lime do not improve, but rather deteriorate, the appearances of oils and other fatty bodies. According to Appert, mixed and subjected to the action of high-pressure steam in a digester, at 250° or 260° F., becomes so hard as to be sonorous when struck, white and capable when made into candles, of giving a superior light. A convenient mode of rendering minced tallow, or melting it, is to put it in a tub, and drive steam through it from numerous orifices in ramifying pipes placed near the bottom. Mr. Watt's plan of purifying fats, patented in March, 1826, has been successful. He employs dilute sulphuric acid, to which he adds a little nitric acid, with a very small quantity of bichromate of potash, to "supply oxygen," and some oxalic acid. These are mixed with the fat in the steaming tub. When the lumps of fat are nearly dissolved, he takes for every ten of fat, one pound of strong nitric acid, diluted with one quart of water; to which he adds two ounces of alcohol, naphtha, sulphuric ether, or spirits of turpentine; and after introducing this mixture, he continues the boiling for half an hour. The fat is finally washed.

Others have proposed to use vegetable or animal charcoal first, especially for rancid oils, then to heat them with a solution of sulphate of copper and common salt, which is supposed to precipitate the fetid albuminous matter.

Mr. Prynne obtained a patent in March, 1840, for purifying tallow for the candle-maker, by heating it along with a solution of carbonate of potash or soda for 8 hours, letting the whole cool, removing the tallow to another vessel, heating it by means of steam up to 206° F., along with dry carbonate of potash (pearlash). Letting this mixture cool very slowly; and finally removing the tallow to a vessel enclosed in steam, so as to expel any subsidiary moisture. — *Newton's Journal*, xxi. 258.

A patent for a like purpose was obtained in June, 1842, by Mr. H. H. Watson. He avails himself of the bleaching power of oxygen, as evolved from permanganate of potash (chameleon mineral), in the act of its decomposition by acids, while in contact with the melted fat. He prescribes a leaden vessel (a well jointed wooden tub will also serve) for operating upon the melted tallow with one-twentieth of its weight of the manganate dissolved in water, and acidulated to the taste. The whole are to be well mixed, and gradually heated from 150° up to 212° F., and maintained at that temperature for an hour. On account of the tendency of the dissolved manganate to spontaneous decomposition, it should be added to the dilute acid, mixed with the fat previously melted at the lowest temperature consistent with its fluidity.

Mr. Wilson, of Vauxhall, has applied centrifugal action to the separation of the liquid from the more solid parts of fatty matters, employing in preference the *hydro-extractors* used by Seyrig and Co. for drying textile fabrics. Mr. Wilson applies a stout cotton twill in addition to the wire-grating; and in order to avoid the necessity of digging the concrete parts, and to prevent them from clogging the interstices for the discharge of the oily matter, he places the whole in a bag 8 inches in diameter, and of such length that when laid on the rotating machine against the grating the two ends will meet. The speed of the machine must be kept below that at which stearic acid or stearine would pass; which is known by the fluidity of the expressed fluid. To take advantage of the liquefying influence of heat, he keeps the temperature of his own room about 2° F. above that of the substances under treatment.

The chemistry of fat will be found in *Ure's Dictionary of Chemistry*. For Imports, see, *see TALLOW*.

FAULTS (*Fautes*, Fr.), in mining, are disturbances of the strata which interrupt the miner's operations, and put him at a loss to discover where the vein of ore or bed of coal has been "thrown" by the convulsion of nature.

A mineral vein, may be regarded as a fissure formed by the consolidation of the rocks in which it exists, or by some movement of the entire mass, producing these cracks at right angles to the line of greatest mechanical force; these have been even-

usually filled in with the mineral or metalliferous matter which we find in them. After this has taken place, there has sometimes been a movement of a portion of the ground, and the mineral vein, or lode, has been fractured. A simple illustration of this is the following, *fig. 736*, where we have the mineral vein dislocated, and subsequently to the dislocation there has been a formation of a string of spathose iron, following the bendings of a crack formed by the movement, which, in this case, has been less than the width of the lode. In the large majority of examples the "heave" or "throw" of the lode has been very considerable. It is usual to speak of a *fault* as if the fissure had actually moved the lode. It should be understood that an actual movement of great masses of the solid earth is implied, and consequently, the *lode* having been formed before the movement, it is moved with the rock in which it is enclosed. *Fig. 739* is the plan of veins 1, 2, 3, 4, and an Elvan course *a a*, which have been dislocated along the line *b, c*, and all the lodes and the Elvan course moved. In this case the movement has probably taken place from the North towards the South. This disturbance will be continued to a great depth, and in *fig. 737* is a section showing the dislocation of a lode into three parts. In

736

737

739

738

this case the movement has probably been the subsidence of that portion of the ground containing the lode *b*, and the further subsidence of that portion containing the lode *a*; the condition of the surface being subsequently altered by denudation. The inclination of a lode is frequently changed by these movements, thus *fig. 730* supposes *cd* to represent the original condition of the lode by a convulsion, the portion *a b* has fallen away leaving a chasm between, and the "dip" or inclination of the lode is therefore materially changed. The direction of the lode is frequently altered by these movements. Many lodes in Cornwall have a direction from the N. of E. to the S. of W. up to a fault, on the other side of which the direction is changed from the S. of E. to the S. of W. Where these disturbances are of frequent occurrence, the difficulties of mining are greatly increased.

The dislocations and obstructions found in coal-fields, which render the search for coal so difficult, and their mining so laborious and uncertain, are the following, —

1. *Dikes.* 2. *Slips or Faults.* 3. *Hitches.* 4. *Troubles.*

The first three, infer dislocation of the strata; the fourth, changes in the bed of coal itself.

1. A *dike* is a wall of extraneous matter, which divides all the beds in a coal-field. Dikes extend not only in one line of bearing through coal-fields for many miles, but run sometimes in different directions, and have often irregular bendings, but no sharp angular turns. When from a few feet to a few fathoms in thickness, they occur sometimes in numbers within a small area of a coal basin, running in various directions, and even crossing each other. Fig. 740, represents a ground plan of a coal-field, intersected with greenstone dikes. *A B* and *C D* are two dikes standing parallel to each other; *K R* and *L O H* are cross or oblique dikes, which divide both the coal strata and the primary dikes *A B* and *C D*.

2. *Slips* or *faults* run in straight lines through coal-measures, and at every angle of incidence to each other. Fig. 741 represents a ground plan of a coal-field, with two slips *A B* and *C D*, the line of bearing of the planes of the strata, which throw them down to the outcrop. This is the simplest form of a slip. Fig. 742, exhibits part of a coal-field intersected with slips, like a cracked sheet of ice. Here *A B* is a dike; while the narrow lines show faults of every kind, producing dislocations varying in amount of slip from a few to a great many fathoms. The faults at the points *a, a, a* vanish; and the lines at *c* denote four small partial slips called *kitches*.

The effects of slips and dikes on the coal strata appear more prominently when viewed in a vertical section, than in a ground plan, where they seem to be merely walls, veins, or lines of demarcation. Fig. 743 is a vertical section of a coal-field.

from dip to rise, showing three strata of coal *a, b, c*. *A B* represents a dike at right angles to the plane of the coal-beds. This rectangular wall merely separates the coal-measures, affecting their line of rise; but farther to the rise, the oblique dike *C D* interrupts the coals *a, b, c*, and not only disjoins them, but has produced a movement which has thrown them and their concomitant strata greatly lower down; but still, with this depression, the strata retain their parallelism and general slope. Nearer to the outcrop, another dike, *K R*, interrupts the coals *a, b, c*, not merely breaking the continuity of the planes, but throwing them moderately up, so as to produce a steeper inclination, as shown in the figure. It sometimes happens that the coals in the compartment *n*, betwixt the dikes *C* and *K*, may lie nearly horizontal, and the effect of the dike *K, R*, is then to throw out the coals altogether, leaving no vestige of them in the compartment *K*.

The effect of slips on the strata is also represented in the vertical section, fig. 744, where *a, b, c* are coals with their associated strata, *A B* is an intersecting slip, which throws all the coals of the first compartment much lower, as is observable in the second, No. 2; and from the amount of the slip, it brings in other coal-seams, marked 1, 2, 3, out in the

compartment No. 1. *c n*, is a slip producing a similar result, but not of the same magnitude; *k r* represents a slip across the strata, reverse in direction to the former, the effect of which is to throw up the coals, as shown in the area No. 4. Such a slip occasionally brings into play seams seated under those marked *a*, *b*, *c*, as seen at 4, 5, 6; and it may happen that the coal marked 4 lies in the prolongation of a well-known seam, as *c*, in the compartment No. 3, when the case becomes puzzling to the miner. In addition to the above varieties, a number of slips or hitches are often seen near one another, as in the area marked No. 5, where the individual displacements are inconsiderable, but the aggregate dislocation may be great, in reference to the seams of the 6th compartment.

745

The results of dikes and slips on a horizontal portion of a field are exemplified in fig. 745. Where the coal-measures are horizontal, and the faults run at a greater angle than 45° to the line of bearing, they are termed "dip" and "rise" faults, as *a n*, *c n*, *c r*. The following fig. 746, which is an accurate section of the Mustyn coal-field, Flintshire, will show the amount to which these disturbances are experienced. The letters mark with sufficient dis-

746

a. Worked out.
b. Ditto
c. 5 yd. coal worked out.
d. 3 yd. ditto.

e. Inferior coal.
f. Ditto
g. Yard coal worked out.
h. 6 ft. coal (intercalated).

i. Main coal, 8 ft. (very good).
j. 3 ft. coal.
k. Stone coal.
l. 3 ft. coal.

747

tinctness the beds on either side of the fault.

Coal viewers or engineers regard the dislocations now described as being subject in one respect to a general law, which may be thus explained:—Let fig. 747 be a portion of a coal-measure *a*, being the pavement and *n* the roof of the coal-seam. If, in pursuing the stratum at *c*, a dike *n* occurs, standing at right angles with the pavement, they conclude that the dike is merely a partition-wall between the beds by its own thickness, leaving the coal-seam undisturbed on either side; but if a dike *r* forms, as at *n*,

conclude that the dike is merely a partition-wall between the beds by its own thickness, leaving the coal-seam undisturbed on either side; but if a dike *r* forms, as at *n*,

an obtuse angle with the pavement, they conclude that the dike is not a simple partition between the strata, but has thrown up the several seams into the predicament shown at G. Finally, should a dike make at an acute angle with the pavement, they conclude that the dike has thrown down the coal measures into the position of K.

Dikes and faults are denominated *upthrow* or *dowthrow*, according to the position they are met with in working the mine. Thus in *fig. 743*, if the miner is advancing to the rise, the dike A is obviously does not change the direction; but C N is a downthrow dike of a certain number of fathoms towards the rise of the basin, and E F is an upthrow dike likewise towards the rise. On the other hand, when the dikes are met with by the miner working from the rise to the dip, the names of the above dikes would be reversed; for what is an upthrow in the first case, becomes a downthrow in the second, relative to the mining operations.

3. We have seen that *hitches* are small and partial slips, where the dislocation does not exceed the thickness of the coal seam; and they are correctly enough called *strips* by the miner. *Fig. 743* represents the operation of the *hitches*

A, B, C, D, E, F, G, H, on the coal-measures. Though observed in one or two seams of a field, they may not appear in the rest, as is the case with dikes and faults.

In the above description the language of the mine has been retained, but in the case of the

dike, as of the *fault-proper*, it is not that the dike has lifted the coal bed up or down, but during the convulsive movements of the earth, when those trap dikes were being forced from below, great movements were produced on either side of the fissures, through which the molten matter ascended, and hence the alteration in the position of the beds, which were previously, perhaps, nearly in a horizontal plane.

FEATHERS. (*Plumes*, Fr.; *Federn*, Germ.) "The most beautiful, the most complex, and the most highly elaborated of all the coverings of animals, due to the development of the epidermal system, is the plumage of birds." — Owen.

A feather consists of the "*quill*," the "*shaft*," and the "*vane*." The vane consists of "*barbs*" and "*barbules*."

The *quill* is pierced by a lower and an upper orifice, and contains a series of light, dry, conical capsules, fitted one upon another, and united together by a central pedicle.

The *shaft* is slightly bent, the concave side is divided into two surfaces by a middle longitudinal line continued from the upper orifice of the quill, the convex side is smooth. Both sides are covered with a horny material similar to that of the quill, and they enclose a peculiar white, soft, elastic substance, called the "*pith*." The *barbs* are attached to the sides of the shaft. The *barbules* are given off from either side of the barbs, and are sometimes similarly barbed themselves, as may be seen in the barbules of the long feathers of the peacock's tail.

The barbules are commonly short and close set, and curved in contrary directions, so that two adjoining series of barbules interlock together and form the mechanism by which the barbs are compacted into the close and resisting vane of the quill, or "*feather*," properly so called. When the barbules are long and loose, they characterise that form of the feather which is properly called a "*plume*," and such are the most valuable products of the plumage of birds in a commercial point of view, as e. g. the plumes of the ostrich.

THE DOWN. — The lower barbs in every kind of feather are usually loose, forming the down, which is increased in most birds by what is called the "*accessory plume*." This is usually a soft downy tuft, but varies in different species, and even in the feathers of different parts of the body of the same bird. The value of feathers for bed stuffing depends upon the proportion of loose soft down that enters into their composition; and as the "*accessory plume*" in the body feathers of the swans, geese, and ducks, is almost as long as the feather from which it springs, hence arises the commercial value of the feathers of those aquatic birds. — Owen.

The first covering of the young bird is a down. In most birds a certain portion of the down feathers is retained with the true feathers, and this proportion is usually greatest in the aquatic birds.

It is most remarkable in the eider duck (*Anas mollissima*). "The down of the eider combines, with its peculiar softness, fineness, and lightness, a great degree of elasticity that the quantity of this beautiful material which might be compressed and concealed between the two hands of a man, will serve to stuff the coverlet of a bed."

— Owen.

Feathers constitute the subject of the manufacture of the *Plumassier*, a name given to the artisan who prepares the feathers of certain birds as ornaments for ladies and for military men, and to him also who combines the feathers in various forms. We shall content ourselves with describing the method of preparing ostrich feathers, as most others are prepared in the same way.

Several qualities are distinguished in the feathers of the ostrich; those of the male, in particular, are whiter and more beautiful. Those upon the back and above the wings are preferred; next those of the wings, and lastly, of the tail. The down is merely the feathers of the other parts of the body, which vary in length from 4 to 14 inches. This down is black in the males, and grey in the females. The finest white feathers of the female have always their ends a little greyish, which lessens their lustre, and lowers their price. These feathers are imported from Algiers, Tunis, Alexandria, Madagascar, and Senegal; thus being the order of their value.

The *sourcing process* is thus performed:—4 ounces of white soap, cut small, are dissolved in 4 pounds of water, moderately hot, in a large basin; and the solution is made into a lather by beating with rods. Two bundles of the feathers, tied with peckthread, are then introduced, and are rubbed well with the hands for five or six minutes. After this soaping they are washed in clear water, as hot as the hand can bear.

The whitening or bleaching is performed by three successive operations.

1. They are immersed in hot water mixed with Spanish white, and well agitated in it; after which they are washed in three waters in succession.

2. The feathers are axed in cold water containing a little indigo tied up in a fine cloth. They should be passed quickly through this bath.

3. They are sulphured in the same way as straw hats are (see *SULPHURING*); they are then dried by hanging upon cords, when they must be well shaken from time to time to open the fibres.

The ribs are scraped with a bit of glass cut circularly, in order to render them very pliant. By drawing the edge of a blunt knife over the filaments they assume the curly form so much admired.

Those feathers which are of a dingy colour are dyed black. For 20 pounds of feathers, a strong decoction is made of 25 pounds of logwood in a proper quantity of water. After boiling it for 6 hours, the logwood is taken out, 5 pounds of copperas are thrown in; and, after continuing the ebullition for 15 or 20 minutes, the copper is taken from the fire. The feathers are then immersed by handfuls, thoroughly soaked, and worked about; and left in two or three days. They are next cleansed in a very weak alkaline lye, and soaped three several times. When they feel very soft to the touch, they must be rinsed in cold water, and afterwards dried. White feathers are very difficult to dye a fine black.

For dyeing other colours, the feathers should be previously well bleached by the action of the sun and the dew; the end of the tube being cut sharp like a toothpick, and the feathers being planted singly in the grass. After fifteen days' exposure, they are cleared with soap as above described.

Rose colour or pink, is given by safflower and lemon juice.

Deep red, by a boiling hot bath of Brazil wood, after aluming.

Crimson. The above deep red feathers are passed through a bath of cudbear.

Fraus de Monsieur. The deep red is passed through an alkaline bath.

Blues of every shade, are dyed with the indigo vat.

Yellow; after aluming, with a bath of turmeric or weld.

Other tints may be obtained by a mixture of the above dyes.

Feathers supply us with a soft elastic down on which we can repose our wearied frames, and enjoy sweet slumbers. Such are called *bed feathers*.

Goose feathers are most esteemed. There is a prejudice that they are best when plucked from the living bird, which is done thrice a year, in spring, midsummer, and the beginning of harvest. The qualities sought for in bed feathers are softness, elasticity, lightness, and warmth. Their only preparation when cleanly gathered are a slight beating to clear away the loose water, but for this purpose they must be first well dried either by the sun or stove. Staving or hot air being also necessary to remove any animal matter liable to putrefy.

The feathers of the elder duck, *Anas mollissima*, called elder down, possess in a superior degree all the good qualities of goose down. It is used only as a covering to beds, and never should be slept upon, as it thereby loses its elasticity.

Quills for writing. These consist usually of the feathers plucked out of the wings of geese. Dutch quills have been highly esteemed, as the Dutch were the first who hit upon the art of preparing them well, by clearing them both inside and outside from a fatty humour with which they are naturally impregnated, and which prevents the ink from flowing freely along the pens made with them. The Dutch for a long time

employed hot cinders or ashes to attain this end; and their secret was preserved very carefully, but it at length transpired, and the process was then improved. A bath of very fine sand must be kept constantly at a suitable temperature, which is about 110° F.; into this the quill end of the feather must be plunged, and left in it a few instants. On taking the feathers out they must be strongly rubbed with a piece of flannel, after which they are found to be white and transparent. Both carbonate of potash in solution and dilute sulphuric acid have been tried to effect the same end, but without success. The yellow tint which gives quills the air of age, is produced by dipping them for a short time in dilute muriatic acid, and then making them perfectly dry. But this process must be preceded by the sand bath operation.

Quills are dressed by the London dealers in two ways; by the one, they remain of their natural colour; by the other, they acquire a yellow tint. The former is called the Dutch method, and the principal workman is called a Dutcher. He sits before a small stove fire, into which he thrusts the barrel of the quill for about a second, then lays its root quickly below his blunt-edged knife, called a hook, and, pressing this firmly with the left hand, draws the quill briskly through with his right. The bed on which the quill is laid to receive this pressure is called the plate. A skilful workman can pass 2000 quills through his hands in a day of ten hours. They are next cleansed by being scrubbed by a woman with a piece of rough dog-fish skin, and then tied up in bundles.

In the goose's wing, the five exterior feathers only are valuable for writing; the first is the hardest and roundest of all, but the shortest; the next two are the best of the five. The heaviest quills are generally the best.

FECHULA (*Pecula*, Fr.; *Stärkemehl*, Germ.) sometimes signifies corn flour, sometimes starch, from whatever source obtained; and it is also applied to chlorophyll, the green matter of plants. The term is applied to any pulverulent matter obtained from plants by simply breaking down the texture, washing with water, and sub-sidence.

FEEDER, a mining term. A small lateral lode falling into the main lode or mineral vein.

FELL. The hide of an animal.

FELL-MONGER. The business of the fellmonger is to separate the wool from the skin. The wool is sold to the woolstapler, and the stripped skins sent to the leather dressers or parchment makers.

FELSPAR (*Orthose*, Fr.; *Feldspath*, Germ.) is a mineral crystallising in oblique rhomboidal prisms, susceptible of two cleavages; lustre more pearly than vitreous; spec. grav. 2.39 to 2.55; scratches glass, but is softer than quartz; yields no water when calcined; fusible at the blowpipe into a white enamel; not affected by acids. The liquid left from its analytical treatment with nitrate of baryta, nitric acid, and carbonate of ammonia affords on evaporation an alkaline residuum which precipitates platinum from its chloride, and appears from this, as well as other tests, to be potash. Felspar consists of silica, 65.75; alumina, 17.50; potash, 12; lime, 1.25; oxide of iron, 0.75. — (*Rose*.) This mineral is a leading constituent of granite; some varieties of which, by the decomposition of the included felspar, furnish the potash or Cornish stone, so much used in the porcelain and best pottery manufactories.

The Felspars may be divided into four groups:—

I. Potash felspar (which often contains some soda); common felspar, or orthoclase; and leucite.

II. Soda felspar (or soda and potash); albite, ryacolite, oligoclase, and nepheline.

III. Soda and lime felspar (containing some potash), andesine, vogsite.

IV. Lime felspar; anorthite, labradorite, thiermaurite.

V. Lithia felspar, or petalite.

I. ORTHOCLASE, the common constituent of granite, of which it ordinarily composes from 40 to 45 per cent; consists of silica, 65.85, alumina, 18.06, potash, 16.99 = 100.00. It is colourless, or pale flesh-coloured, or yellow. The name is generally restricted to the subtranslucent varieties, there being many sub-varieties founded on variations of lustre, colour, &c., to which other names have been given. Amongst the varieties so comprehended under the general name of orthoclase, the principal are adularia, transparent or translucent felspars found in large crystals in granitic rocks. Moonstone and sunstone are varieties of adularia, which are described under their proper letters. In addition to potash, some specimens of adularia contain more than four per cent. of soda.

GLASSY FELSPAR (*Schalin*, ice-spar in part), occurs crystallised in the form of a clear transparent glass in trachytic and volcanic rocks.

Mr. SCHUMMERT, named after the distinguished geologist and founder of the Silurian system, is a yellowish-grey or flesh-red felspar from Hawliab, and from Heavirree, near Exeter.: It is remarkable for its opalescence.

FAITHARTH is a flesh-coloured felspar, occurring in amygdaloid near Kilpatrick. It contains 3 per cent. of magnesia.

LEUCITE is not so hard as orthoclase, is transparent and infusible. It occurs in detached trapezohedral crystals of a white colour, which, from the similarity of their forms to the common variety of garnet, have obtained the name of "white garnet." It is found abundantly in trachyte on the Rhine, between Lake Laach and Andernach, and also in the older lavas of Vesuvius, some of which appear to be almost entirely composed of it. "The leucitic lavas, of the neighbourhood of Rome, have been used, for the last 2000 years at least, in the formation of millstones."—*Dana*.

It is composed of silica, 55.1; alumina, 23.4; potash, 21.5 = 100.0.

II. ALBITE, or *Clearcelandite* is frequently a constituent of granite, and, more frequently than common felspar, of syenite and greenstone; but it often occurs associated with the latter in the same granite, when it may be distinguished by its greater whiteness and translucency. It is composed of silica, 68.7; alumina, 12.5; soda, 11.8 = 100.0.

TRICOLITE is supposed by Rose to be a mixture of felspar and nepheline. It resembles glassy felspar, and occurs in doubly oblique rhombic prisms. It consists of silica, 51.66; alumina, 27.66; lime, 1.30; soda, 11.60; potash, 4.58 = 100.00.

It is found in the trachytes of Bohemia and Hungary, in the lavas of Vesuvius, and in pitchstone in the islands of Arran and Rum.

OLIOCLASE, or *soda apodumene*, consists of silica, 62.3; alumina, 23.5; soda, 14.2 = 100.0. It occurs in porphyry, granite, syenite, serpentine, and basalt. At Teneriffe it is met with in trachyte.

NEPHELINE, or *Rhomboidal felspar*, occurs in six-sided prisms, and is composed of silica, 44.4; alumina, 33.6; soda, 16.9; potash, 5.1 = 100.0.

The name nepheline includes the crystallized varieties from Vesuvius, while, under the name lilacite, are comprised the coarser massive varieties with a greasy lustre. It is found in the older lavas of Vesuvius, and in the lava of Capo di Torre, near Rome.

III. AEGYRINE occurs in a whitish syenite in the Aoden, in the Vosges, and elsewhere. It consists of silica, 60.16; alumina, 23.86; peroxide of iron, 1.65; magnesia, 0.84; lime, 5.91; soda, 6.58; potash, 1.00 = 100.00.

FINGITS is Labradorite rendered hyaline by partial alteration. It is of a whitish colour, sometimes with a shade of green or blue, and has a pearly or greasy lustre. It consists of silica, 49.32; alumina, 30.07; peroxide of iron, 0.70; protoxide of manganese, 0.60; lime, 4.25; magnesia, 1.96; soda, 1.85; potash, 4.45; water, 3.13 = 99.25.—(*Delesse*.) Found in the porphyry of Ternay in the Vosges.

IV. ANORTHITE occurs in white translucent or transparent crystals, with a vitreous lustre, inclining to pearly on the planes of cleavage. It consists of silica, 43.2; alumina, 36.8; lime, 20.0. Occurs among the old lavas of Vesuvius in the ravines of Monte Somma, and in the island of Procida, in the bay of Naples. It has also lately been found by Professor Haughton, in syenitic dykes traversing limestone (forming 53 per cent. of the rock), near Carlingford in Ireland.

THORAUURITE is an Icelandic variety of anorthite, and consists of silica, 48.36; alumina, 30.59; peroxide of iron, 1.37; magnesia, 0.57; protoxide of manganese, a trace; lime, 17.16; soda, 1.13; potash, 0.62 = 100.20.—*Genth*.

LABRADORITE, or *Labrador felspar*, consists of silica, 53.69; alumina, 29.63; lime, 12.13; soda, 4.50 = 100.00.

It occurs principally as a constituent of other rocks, in the lavas of Etna and Vesuvius, in the oriental verde antique of Greece and other porphyries, as well as in certain hornblende rocks, granites, and syenites. On the coast of Labrador, whence it was originally brought, it is associated with hornblende, hypersthene, and magnetic iron ore. Labradorite receives a fine polish, and on account of its beautiful chatoyant reflections, it is valued for ornamental purposes and sometimes used in jewellery. The parts exhibiting the varied play of colours are disposed in irregular spots and patches, and the same spot, if held in different positions, displays various tints, of which violet and red are the most rare.

The play of colours is supposed to be produced by microscopic crystals of quartz imbedded in the stone. (?)

It is manufactured into brooches, bracelets, snuff-boxes, &c. It looks best when cut in plain, very flat cabochon, and a great deal of skill is required to divide the stone in such a manner that the iridescent portions (on which its beauty depends) may be displayed to the utmost advantage.

V. PETALITE is remarkable as being the mineral in which Arfvedson first discovered *lithia*. It is white, frequently with a reddish tinge, and possesses a glistening lustre and a lamellar structure. Translucent. Not affected by acids. Emits a blue phosphorescent light when gently heated.

It consists of silica, 77.9; alumina, 17.7; lithia, 3.1; soda, 1.3 = 100.0. The only

known European locality is the iron mine of Udön, an island 35 miles S. E. of Stockholm. It is found in the United States, and in Upper Canada, near York, on Lake Ontario.

FELSPATHIC. (*Of* or belonging to *fel* *pat*.)

FELTING (*Feutrage*, Fr.; *Filzen*, Germ.) is the process by which loose flocks of wool, and hairs of various animals, as the beaver, rabbit, hare, &c., are mutually interlaced into a compact textile fabric. The first step towards making felt is to mix, in the proper proportions, the different kinds of fibres intended to form the stuff; and then, by the vibratory strokes of the bowing ring, to toss them up in the air, and to cause them to fall as irregularly as possible, upon the table, opened, spread, and scattered. The workman covers this layer of loose flocks with a piece of thick blanket stuff slightly moistened; he presses it with his hands, moving the hairs backward and forwards in all directions. Thus the different fibres get interlaced; by their ends pursuing ever tortuous paths; their vermicular motion being always, however, root foremost. As the matting gets denser, the hand pressure should be increased in order to overcome the increasing resistance to the decussation.

A first thin sheet of soft spongy felt being now formed, a second is condensed upon it in like manner, and then a third, till the requisite strength and thickness be obtained. These different pieces are successively brought together, disposed in a way suitable to the wished-for article, and united by continued dextrous pressure. The stuff must be next subjected to the fulling mill. See **HAT MANUFACTURE**, under which head the process of felting is described.

FERMENT (Eng. and Fr.; *Hefe*, Germ.) is the substance which, when added in a small quantity to vegetable or animal fluids, tends to excite those intestine motions, and changes, which accompany fermentation. It seems to be the result of an alteration which vegetable albumen and gluten undergo with contact of air amidst a fermenting mass. The precipitates or lees which fall down, when fermentation is finished, consist of a mixture of the fermenting principle with the insoluble matters contained in the fermented liquor, some of which, like *hordewort*, existed in the wort, and others are probably generated at the time.

To prepare a pure ferment, or at least a compound rich in that principle, the precipitate separated during the fermentation of a clear infusion of malt, commonly called yeast or barm, is made use of. This party matter must be washed in cold distilled water, drained and squeezed between the folds of blotting paper. By this treatment it becomes a pulverulent mass, composed of small transparent grains, yellowish grey when viewed in the compound microscope. It contains much water, and is therefore soft, like moist gluten and albumen. When dried it becomes, like these bodies, translucent, yellowish brown, horny, hard, and brittle. In the soft humid state it is insipid, inodorous, insoluble in water and alcohol. If in this state the ferment be left to itself, at a temperature of from 60° to 70° F., but not in too dry a situation, it putrefies with the same phenomena as vegetable gluten and albumen, and leaves, like them, a residuum resembling old cheese. See **FERMENTATION** and **YEAST**.

FERMENTATION. (*Fermentation*, Fr.; *Gährung*, Germ.) A change which takes place, under the influences of air and moisture at a certain temperature, in the constituent particles of either vegetable or animal substances. This change is indicated by a sensible internal motion—the development of heat—the evolution of gaseous products. Fermentation may be divided into several kinds, as—

Saccharine,	Butylic,
Acetic,	Glyceric,
Alcoholic or Vinous,	Lactic,
Putrefactive,	Mucous.

(Of the latter examples but a brief notice is required. *Mucous fermentation* is established when the juice of the beetroot or carrot is kept at a temperature of 100° for some time, when a tumultuous decomposition takes place. All the sugar disappears, and the liquor is found to contain a large quantity of gum, and of mannite with lactic acid.

Lactic Fermentation.—If a solution of one part of sugar in five parts of water be made to ferment, by the addition of a small quantity of cheese or animal membrane, at a temperature of 90° or 100°, lactic acid is formed, which may be separated by adding a little chalk, the lactate of lime depositing in crystalline grains. In lactic fermentation mannite invariably is produced as a secondary product, the formation of which is not explained. It has been suggested that the formation of mannite is connected with the production of succinic acid, which Schmidt, in a letter to Liebig, states that he has found in fermenting liquids containing sugar. He suggests the following formula:—

Glyceric Fermentation.—When glycerine is mixed with yeast, and kept in a warm place for some weeks, it is decomposed and converted into *metacetic acid*. This fermentation resembles the last named. The glycerine, $C^3H^5O^3$, forming metacetic acid, $C^3H^3O^3$, as sugar, $C^6H^{12}O^6$, does lactic acid, $C^3H^5O^3$, by loss of the elements of water.—*Karr.*

Butyric Fermentation.—If the lactic fermentation is allowed to proceed beyond the point indicated for the formation of lactate of lime, the precipitate in part redissolves with a very copious evolution of hydrogen gas, and carbonic acid, and the liquor contains butyrate of lime. In this action two atoms of lactic acid, $C^3H^5O^3$, produce butyric acid, $C^4H^7O^2$, carbonic acid, and hydrogen gas.

Putrefactive Fermentation. See PUTREFACTION.

The three first named kinds of fermentation demand a more especial attention from their importance as processes of manufacture. Under the heads respectively—ACETIC ACID, BEER, BREWING, DISTILLATION, MALT, and WINE, will be found everything connected with the practical part of the subject; we have therefore only now to deal with the chemical and physical phenomena which are involved in the remarkable changes which take place. When vegetable substances are in contact with air and moisture, they undergo a peculiar change (*decomposition*). Oxygen is absorbed and carbonic acid and water are given off, while there is a considerable development of heat. This may take place with greater or less rapidity, and thus *ermentous*, fermentation, or combustion may be the result; the spontaneous ignition of hay (as an example) being the final action of this absorption of oxygen.

Saccharine Fermentation.—If starch, $C^6H^{10}O^5 + 2H^2O$, be moistened with an infusion of pale malt, it is rapidly converted into dextrine, $C^{12}H^{20}O^{10}$, and hence into grape sugar, $C^{12}H^{22}O^{11}$; this is especially called the *saccharine fermentation*, since sugar is the result.

Acetic and Alcoholic Fermentation.—If sugar is dissolved in water, it will remain perfectly unaltered if the air is excluded; but if exposed to the air, a gradual decomposition is brought about, and the solution becomes brown and sour. Oxygen has been absorbed, and acetic acid produced. If, however, the sugar is brought into contact with any organic body which is in this state of change, the particles of the sugar participate in the process, carbonic acid is evolved, and *alcohol* produced. There are some substances which are more active than others in producing this change. Yeast is the most remarkable; but blood, white of egg, glue, and flesh, if they have begun to putrefy, are capable of exciting fermentation; vegetable albumen and gluten being, however, more active. Vegetable albumen, gluten, and legumin differ from most vegetable bodies in the large quantity of nitrogen which they contain. These substances exist in all fruits, and hence, when fruit is crushed, the sugar of the juices in contact with the albumen or gluten being then exposed to the air, oxygen is rapidly absorbed, the nitrogenous body begins to putrefy, and the sugar passes into fermentative activity. The necessity for oxygen is at the commencement of the decomposition; when the putrefaction of the albumen or gluten has once begun, it extends throughout the mass without requiring any further action of the air. These may be regarded as natural ferments. Yeast is an artificial one. This body will be more particularly described. See YEAST.

To produce a vinous liquid, it is necessary that there shall be present sugar, or some body, as starch or gum capable of conversion into sugar, a certain portion of water, and some ferment—for all practical purposes *yeast*; and the temperature should be steadily maintained at about $80^\circ F$. Both cane and grape sugar yield alcohol by fermentation, but Liebig considers that cane sugar, before it undergoes vinous fermentation, is converted into grape sugar by contact with the ferment; and that, consequently, it is grape sugar alone which yields alcohol and carbonic acid.

Grape sugar, as dried at 312° , contains exactly the elements of two atoms of alcohol and four of carbonic acid. As $2(C^6H^{12}O^6)$ and $4CO^2$ arise from $C^{12}H^{22}O^{11}$.

Cane sugar takes an atom of water to form grape sugar. It follows therefore that cane sugar should in fermenting yield more than its own weight of carbonic acid and alcohol; and it has been ascertained by experiment that 100 parts actually give 114, whilst by theory 105 should be produced, consisting of 51.3 of carbonic acid, and 53.7 of alcohol.—(*Karr.*) Dr. Pereira has given the following very intelligible arrangement to exhibit these changes:—

MATERIAL.		COMPOSITION.	
1 equivalent of crystallized cane sugar	171	4 eq. carbon 36	4 eq. carbonic acid . . . 84
1 equivalent of . . .	171	8 .. carbon 48	
1 equivalent of . . .	171	8 .. oxygen 64	
1 equivalent of water . . .	9	4 .. oxygen 32	
		12 .. hydrogen 12	eq. alcohol . . 53.7
	180		180

These facts will sufficiently prove that vinous or alcoholic fermentation is but a metamorphosis of sugar into alcohol and carbonic acid.

Such are the generally received views. We find, however, some other views promulgated which it is important to notice.

Liebig calls *putrefactive fermentation*,—every process of decomposition which, caused by external influences to any part of an organic compound, proceeds through the entire mass without the further co-operation of the original cause. *Fermentation*, according to Liebig's definition, is the decomposition exhibited in the presence of putrefying substances or ferments, by compounds nitrogenous or non-nitrogenous, which alone are not capable of putrefaction. He distinguishes, in both putrefaction and fermentation, processes in which the oxygen of the atmosphere continually co-operates, from such as are accomplished without further access of atmospheric air.

Liebig opposes the view which considers putrefaction and fermentation as the result of vital processes, the development of vegetable formations or of microscopic animals. He adduces that no traces of vegetal formations are perceptible in milk which is left for some time in vessels carefully tied over with blotting paper, not even after fermentation has regularly set in, a large quantity of lactic acid having been formed. He further remarks of fermentative processes, that alcoholic fermentation having been observed too exclusively, the phenomena have been generalised, while the explanation of this process ought to be derived rather from the study of fermentative phenomena of a more general character.

Blondeau propounds the view that every kind of fermentation is caused by the development of fungi. Blondeau states that alcoholic fermentation is due to a fungus which he designates *Torula cerevisia*; whilst another, *Penicillium glaucum*, gives rise to lactic fermentation. The latter fermentation follows the former in a mixture of 30 grm. of sugar, 10 grm. of yeast, and 200 c.c. of water, which has undergone alcoholic fermentation at a temperature of about 20°, being terminated in about two days. Beer yeast, when left in contact with water in a dark and moist place, contains, according to Blondeau, germs both of *Torula cerevisia*, and of *Penicillium glaucum*; the former can be separated by a filter, and will induce alcoholic fermentations in sugar water, whilst the latter are extremely minute, and pass through the filter; the filtrate, mixed with sugar water, gives rise to lactic fermentation. Acetic fermentation is due to the development of *Torula aceti*; sugar is converted into acetic acid, without evolution of gas, if 500 grm. dissolved in a litre of water, be mixed with 200 grm. of casein, and confined in contact for a month at a temperature of about 20°. The conversion of nitrogenous substances into fat (for instance, of casein, in the manufacture of Roquefort cheese; of fibrin under similar circumstances), which Blondeau designates by the term fatty fermentation (*fermentation ad pepsin*), is caused by *Penicillium glaucum* or *Torula oryza*; and the former fungus is stated to act likewise in butyric and in urea-fermentation (conversion of the urea into a carbonate of ammonia).

Opposed to this view Schubert has published an investigation upon yeast. In order to prove that the action of yeast is due merely to its porosity, he founds his investigation upon some experiments of Brande (particularly in reference to the statement that fermentation taking place in a solution of sugar in contact with porous bodies is due to an impurity of sugar; according to which various porous bodies, such as charcoal, paper, flowers of sulphur, &c., to which some bicarbonate of ammonia is added, are capable of inducing fermentation in a solution of raw sugar. His observations are also based upon some experiments of his own, which seem to indicate that porous bodies, even without the addition of a salt, are capable of exciting fermentation in a solution of (pure?) cane sugar. Whatever may be the means whereby alcoholic fermentation is induced, he states it to be indispensable that the body in question should be exposed for some time to the influence of air, and that oxygen and carbonic acid are absorbed by the ferment. Both oxygen and carbonic acid, being electro-negative substances, stand in opposition to the electro-positive alcohol, and therefore predispose its formation, but only when they are highly attracted by the powerful surface attraction of the yeast, or of any porous body. The electrical tension, he states, may be increased by many salts, provided that the latter do not at the same time chemically affect either the sugar or the ferment.

C. Schmidt has communicated the results of his experiments to the *Annalen Chem. Pharm.* After stating numerous experiments, he continues: "Nor are fungi the *primarii moventes* of saccharic fermentation; the clear filtrate obtained by filtering almonds crushed in water upon a moist filter, soon induces fermentation in a solution of urea and of grape sugar; in the latter case, no trace of ferment can be discovered under the microscope, not even after fermentation is fully developed. If the solution, still containing sugar, is allowed to stand eight days or a fortnight after fermentation has ceased, an exuberant development of cellular aggregations is ob-

served, but no putrefaction ensues; the fungi, well washed and introduced into a fresh solution of grape sugar, continue to grow luxuriantly, indicating, however, if at all, but very weak fermentation, which rapidly ceases; hence the growth of fungi during fermentative processes is but a secondary phenomenon. The increase of the ordinary ferment, which occurs after yeast has been in contact with sugar, arises from a development of ferment cellulose, which probably takes place at the expense of the sugar. If muscle, gelatine, yeast, &c., in a very advanced state of putrid decomposition be introduced into a solution of 1 sugar in 4 water, all phenomena of putrefaction disappear: after a few hours, active fermentation sets in, ferment cells being formed, and the liquid contains alcohol, but no murex. The inactivity of crushed yeast is due, not to the destruction of the fungi, but to the chemical changes which are induced in yeast during the considerable time necessary for complete comminution. The crushed cells, introduced into sugar water, give rise to the production of lactic acid, without evolution of gas. Schmidt is of opinion that fermentation is a process analogous to the formation of ether. He believes that one of the constituents of yeast, together with the elements of grape sugar, gives rise to the formation of one or several compounds, which are decomposed *in statu nascendi* (like sulpho-vinic acid), splitting into alcohol and carbonic acid.

We believe that the preceding paragraphs fairly represent the views which have been promulgated upon the phenomena of change, which are in many respects analogous to those of combustion and of vitality, presented in the fermentative processes. Much has been done, but there are still some points which demand the careful attention of the chemist.

In a practical point of view, the question which arises from the alteration in the specific gravity of the fluid by fermentation is a very important one, a knowledge of the original gravity of beer being required to fix the drawback allowed upon beer when exported, according to the terms of 10 Vict. c. 5. By this act a drawback is granted of 5s. per barrel of thirty-six gallons, upon beer exported, of which "the worts used *before fermentation* were not of less specific gravity than 1·051, and not greater specific gravity than 1·081," and a drawback of 7s. 6d. per barrel upon beer of which "the worts used *before fermentation* were not of less specific gravity than 1·081." The brewer observes the original gravity of his worts by means of some form of the hydrometer, and preserves a record of his observation. The revenue officer has only the beer, from which he has to infer the original gravity. From the great uncertainty which appeared to attend this question, Professors Graham, Hofmann, and Redwood were employed by the Board of Inland Revenue to discover how the original gravity of the beer might be ascertained most accurately from the properties of the beer itself. When worts are fermented, the sugar passes into alcohol, and they lose in density, and assume as beer a different specific gravity. The gravity of the wort is called the *original gravity*—that of the beer, *beer gravity*. The report of Graham, Hofmann, and Redwood, upon "original gravities," may be supposed to be in the hands of every brewer; but as some of the points examined materially explain many of the phenomena of vinous fermentation, we have transferred a few paragraphs to our pages:—

"As the alcohol of the beer is derived from the decomposition of saccharine matter only, and represents approximately double its weight of starch sugar, a speculative original gravity might be obtained by simply increasing the extract gravity of the beer by that of the quantity of starch sugar known to be decomposed in the fermentation. The inquiry would then reduce itself to the best means of ascertaining the two experimental data, namely, the extract gravity and the proportion of alcohol in the beer, particularly of the latter. It would be required to decide whether the alcohol should be determined from the gravity of the spirits distilled from the beer; by the increased gravity of the beer when its alcohol is evaporated off; by the boiling point of the beer, which is lower the larger the proportion of alcohol present; or by the refracting power of the beer upon light—various methods recommended for the valuation of the spirits in beer.

"Original gravities so deduced, however, are found to be useless, being in error and always under the truth, to an extent which has not hitherto been at all accounted for. The theory of brewing, upon a close examination of the process, proves to be less simple than is implied in the preceding assumption; and other changes appear to occur in worts, simultaneously with the formation of alcohol, which would require to be allowed for before original gravities could be rightly estimated. It was found necessary to study the gravity in solution of each by itself, of the principal chemical substances which are found in fermented liquids. These individual gravities defined the possible range of variation in original gravity, and they brought out clearly for the first time the nature of the agencies which chiefly affect the result.

"The use of cane sugar is now permitted in breweries, and the solution of sugar

may be studied first as the wort of simplest composition. The tables of the specific gravity of sugar solutions, constructed by Mr. Holm, have been verified, and are entirely trustworthy. The second is the first and third columns of Table 1, which figures are, however, from the same source. It is to be remarked that the numbers have all referred to weight and not to measure. A solution of cane sugar, which contains 25 grains of sugar in 100 grains of the fluid, has a specific gravity of 1.0101, referred to the gravity of pure water taken as 1000; a solution of 50 grains of cane sugar in 100 grains of the fluid, a specific gravity of 1.0202, and so on. The proportion of carbon contained in the sugar is expressed in the second column, the numbers being obtained from the calculation that 171 parts by weight of cane sugar ($C_{12}H_{22}O_{11}$) consists of 72 parts of carbon, 11 parts of hydrogen, and 88 parts of oxygen; or of 72 parts of carbon combined with 99 parts of the elements of water. It is usual to keep this in view the proportion of carbon in sugar solutions, as that element is not involved in several of the changes which precede or accompany the principal change which sugar undergoes during fermentation, and which changes only affect the proportions of the oxygen and hydrogen, or elements of water, combined with the carbon. The proportion of oxygen and hydrogen in the altered sugar increases or diminishes during the changes referred to; but the carbon remains constant, and affords, therefore, a fixed term in the comparison of different solutions.

TABLE 1. — Specific gravity of solutions of Cane-sugar in water.

Cane-sugar, in 1000 parts by weight.	Carbon in 1000 parts by weight.	Specific Gravity.
25	10.63	1.0101
50	21.05	1.0202
75	31.58	1.0303
100	42.10	1.0406
125	52.63	1.051
150	63.16	1.0618
175	73.68	1.0729
200	84.21	1.0838
225	94.73	1.0953
250	105.26	1.1067

"When yeast is added to the solution of cane sugar in water, or to any other saccharine solution, and fermentation commenced, the specific gravity is observed to fall, owing to the escape of carbonic acid gas, and the formation of alcohol, which is specifically lighter than water; 171 grains of sugar, together with 99 grains of water, being converted into 99 grains of alcohol and 65 grains of carbonic acid ($C_{12}H_{22}O_{11} + H_2O = 2C_2H_5O + 4CO_2$). But if the process of fermentation be closely watched, the fall of gravity in cane sugar will be found to be preceded by a gradual increase of gravity. Solutions were observed to rise from 1.045 to 1.052, or 3 degrees of gravity, within an hour after the addition of the yeast, the last being in the usual proportion for fermentation. When the yeast was mixed in minute quantity only, such as one-tenth of the weight of the sugar, the gravity of the sugar solution rose gradually in four days from 1.053 to 1.05791, or also nearly 3 degrees; with no appearance at the same time, of fermentation or of any other change in the solution. This remarkable increase of density is owing to an alteration which takes place in the constitution of the cane sugar, which combines with the elements of water and becomes starch sugar, a change which had been already proved by H. Rose and by Dubrunfaut to precede the vinous fermentation of cane sugar. The same conversion of cane sugar into starch sugar, with increase of specific gravity, may be shown by means of acids as well as of yeast. A solution of 1000 parts of cane sugar in water, having the specific gravity 1.05464, became with 1 part of crystallised oxalic acid added to it 1.0577; and being afterwards heated for twenty-three hours at a temperature not exceeding 125° Fahr., it was found (when cooled) to have attained a gravity of 1.0763—an increase again of nearly 3° of gravity."

The difference between the gravities of solutions of cane sugar and starch sugar are of great practical value, but these must be studied in the original, the result however being "that the original gravity of a fermented liquid or beer must be different, according as it was derived from a wort of cane sugar or of starch sugar."

The gravity of malt wort was determined to be intermediate between that of pure cane sugar and starch sugar, and solutions containing an equal quantity of carbon exhibited the following gravities:—

Cane sugar - 1.0729

Pale malt - 1.0742

Starch sugar - 1.0760

Two other substances were found to influence the original gravity of the wort: dextrin, or the gum of starch, and caramel. Tables are given of the specific gravities of these, from which the following results have been deduced:—

Starch sugar	-	-	-	1076
Dextrin	-	-	-	1066.9
Caramel	-	-	-	1062.3

Caramel is stated to interfere more than dextrin in giving lightness or apparent attenuation to fermented worts, without a corresponding production of alcohol.

Another constituent of malt wort, which should not be omitted, is the soluble azotised or albuminous principle derived from the grain. The nitrogen was determined in a strong wort of pale malt with hops, of the specific gravity 1084, and containing about 21 per cent. of solid matter. It amounted to 0.217 per cent. of the wort, and may be considered as representing 3.43 per cent. of albumen. In the same wort, after being fully fermented, the nitrogen was found to amount to 0.134 per cent., equivalent to 2.11 per cent. of albumen. The loss observed of nitrogen and albumen may be considered as principally due to the production and growth of yeast, which is an insoluble matter, at the cost of the soluble albuminous matter. Solutions of egg-albumen in water, containing 3.43 and 2.11 per cent. respectively of that substance, were found to have the specific gravities of 1004.2 and 1003.1. Hence a loss of density has occurred during fermentation of 1.1 degree on a wort of 1084 original gravity, which can be referred to a change in the proportion of albuminous matter. It will be observed that the possible influence of this substance and of the greater or less production of yeast during fermentation, upon the gravity of beer, are restricted within narrow limits."

The reporters' proceed:—

"The process required for the determination of the original gravity of beer, must be easy of execution, and occupy little time. It is not proposed, in the examination of a sample, to separate by chemical analysis the several constituents which have been enumerated. In fact, we are practically limited to two experimental observations on the beer, in addition to the determination of its specific gravity.

"One of these is the observation of the amount of solid or extractive matter still remaining after fermentation, which is always more considerable in beer than in the completely fermented wash of spirits. A known measure of the beer might be evaporated to dryness, and the solid residue weighed, but this would be a troublesome operation, and could not indeed be executed with great accuracy. The same object may be attained with even a more serviceable expression for the result, by measuring exactly a certain quantity of the beer, such as four fluid ounces, and boiling it down to somewhat less than half its bulk in an open vessel, such as a glass flask, so as to drive off the whole alcohol. The liquid when cool is made up to four fluid ounces, or the original measure of the beer, and the specific gravity of this liquid is observed. It has already been referred to as to the extract gravity of the beer, and represents a portion of the original gravity. Of a beer of which the history was known, the original gravity of the malt wort was 1121, or 121°; the specific gravity of the beer itself before evaporation, 1045; and the extract gravity of the beer 1036.7, or 56.7°.

"The second observation which can be made with sufficient facility upon the beer, is the determination of the quantity of alcohol contained in it. This information may be obtained most directly by submitting a known measure of the beer to distillation, continuing the ebullition till all the alcohol is brought over, and taking care to condense the latter without loss. It is found in practice that four ounce-measures of the beer form a convenient quantity for the purpose. This quantity is accurately measured in a small glass flask, holding 17.50 grains of water when filled up to a mark in the neck. The mouth of the small retort containing the beer is adapted to one end of a glass tube-condenser, the other end being bent and drawn out for the purpose of delivering the condensed liquid into the small flask previously used for measuring the beer. The spirituous distillate should then be made up with pure water to the original bulk of the beer, and the specific gravity of the last liquid be observed by the weighing bottle, or by a delicate hydrometer, at the temperature of 60° Fahr. The lower the gravity the larger will be the proportion of alcohol, the exact amount of which may be learned by reference to the proper tables of the gravity of spirits. The spirit gravity of the beer already referred to proved to be 9.525; or it was 1145° of gravity less than 1000, or water. The 'spirit indication' of the beer was therefore 14.05°; and the extract gravity of the same beer 56.7°.

"The spirit indication and extract gravity of any beer being given, do we possess data sufficient to enable us to determine with certainty the original gravity? It has already been made evident that these data do not supply all the factors necessary for reaching the required number by calculation.

"The formation of the extractive matter, which chiefly disturbs the original gravity, increases with the progress of the fermentation; that is, with the proportion of alcohol in the fermenting liquor. But we cannot predicate from theory any relation which the formation of one of these substances should bear to the formation of the other, and are unable, therefore, to say beforehand that because so much sugar has been converted into alcohol in the fermentation, therefore so much sugar has also been converted into the extractive substance. That a uniform, or nearly uniform relation, however, is preserved in the formation of the spirit and extractive substance in beer brewing, appears to be established by the observations which follow. Such an uniformity in the results of the vinous fermentation is an essential condition for the success of any method whatever of determining original gravities, at least within the range of circumstances which affect beer brewing. Otherwise two fermented liquids of this class, which agree in giving both the same spirit indication and the same extractive gravity, may have had different original gravities, and the solution of our problem becomes impossible."

The following table, one of several of equal value, gives the results of a particular fermentation of cane sugar. "Fifteen and a half pounds of refined sugar were dissolved in 10 gallons of water, making 10½ gallons of solution, of which the specific gravity was 1055·3 at 60°; and after adding three fluid pounds of fresh porter yeast, the specific gravity was 1055·95. The original gravity may be taken as 1055·3 (35·3°).

TABLE II. — *Fermentation of Sugar-Wort of original gravity 1055·3.*

i. Number of Observation.	ii. Period of Fermentation.		iii. Degrees of Spirit Indication.	iv. Degrees of Extract Gravity.	v. Degrees of Extract Gravity lost.
	Days.	Hours.			
1	0	0	0	55·50	0·
2	0	6	1·59	52·12	3·38
3	0	12	2·57	47·82	7·68
4	0	19	3·60	43·62	11·88
5	0	27	4·53	40·13	15·37
6	1	5	5·31	35·50	19·90
7	1	12	6·26	31·39	24·11
8	1	19	7·12	27·63	27·87
9	2	11	8·59	29·26	26·24
10	3	11	9·87	13·40	41·90
11	5	12	10·97	7·60	47·90
12	6	12	11·27	4·15	51·35

"Columns iii and v, respectively exhibit the spirit which has been produced, and the solid matter which has disappeared; the first in the form of the gravity of the spirit, expressed by the number of degrees it is lighter than water, or under 1000, and the second by the fall in gravity of the solution of the solid matter remaining below the original gravity 1055·3. This last value will be spoken of as 'degrees of gravity lost.' It is always obtained by subtracting the extract gravity (column iv.) from the known original gravity. To discover whether the progress of fermentation has the regularity ascribed to it, it was necessary to observe whether the same relation always holds between the columns of 'degrees of spirit indication' and 'degrees of gravity lost.' It was useful, with this view, to find what degrees lost corresponded to whole numbers of degrees of spirit indication. This can be done safely from the preceding table, by interpolation, where the numbers observed follow each other so closely. The corresponding degrees of spirit indication and of gravity lost, as they appear in this experiment upon the fermentation of sugar, are as follows:—

TABLE III. — *Fermentation of Sugar-Wort of original gravity 1055·3.*

Degrees of Spirit Indication.	Degrees of Extract Gravity lost.	Degrees of Spirit Indication.	Degrees of Extract Gravity lost.
1	1·71	7	27·01
2	4·74	8	31·87
3	9·26	9	37·12
4	13·44	10	42·88
5	18·00	11	47·89
6	22·54		

" In two other fermentations of cane sugar, the degrees of gravity lost, found to correspond to the degrees of spirit indication, never differed from the numbers of the preceding experiment, or from one another, more than 0.9° of gravity lost. This is a sufficiently close approximation.

" The following table is of much importance :—

TABLE IV.—STARCH-SUGAR.

Degrees of Spirit Indication, with corresponding degrees of gravity lost.

Besides the degrees of gravity lost corresponding to whole degrees of spirit indication, the degrees of gravity lost corresponding to tenths of a degree of spirit indication are added from calculation.

Degrees of Spirit Indication.	0	1	2	3	4	5	6	7	8	9
0	—	2	3	5	7	9	10	12	14	16
1	1.9	2.1	2.4	2.7	3.0	3.3	3.6	3.9	4.2	4.6

10	42.4	42.9	43.4	44.0	44.5	45.0	45.6	46.1	46.6	47.2
11	47.7									

" It is seen from this table that for 6° of spirit indication, the corresponding degrees of gravity lost are 18.3° . For 5.9° of spirit indication, the corresponding degrees of gravity lost are 22.2° .

" This table is capable of a valuable application, for the sake of which it was constructed. By means of it, the unknown original gravity of a fermented liquid or beer from cane sugar may be discovered, provided the spirit indication and extract gravity of the beer are observed. Opposite to the spirit indication of the beer in the table, we find the corresponding degrees of gravity lost, which lost, added to the extract gravity of the beer, gives its original gravity.

" Suppose the sugar beer exhibited an extract gravity of 7.9° (1007.9), and spirit indication of 11° . The latter marks, according to the table, 47.7° of gravity lost, which added to the observed extract gravity, 7.9° , gives 55.6° of original gravity for the beer (1055.6)."

Similar tables are constructed for starch sugar, and for various worts with and without hops.

After explaining many points connected with the problem, as it presented itself under varied conditions as it respected the original worts, the Report proceeds :—

" The object is still to obtain the spirit indication of the beer. The specific gravity of the beer is first observed by means of the hydrometer or weighing bottle. The extract gravity of the beer is next observed as in the former method; but the beer for this purpose may be boiled in an open glass flask till the spirits are gone, as the new process does not require the spirits to be collected. The spiritless liquid remaining is then made up to the original volume of the beer as before. By losing its spirits, the beer of course always increases in gravity, and the more so the richer in alcohol the beer has been. The difference between the two gravities is the new spirit indication, and is obtained by subtracting the beer gravity from the extract gravity, which last is always the higher number.

" The data in a particular beer were as follows :—

Extract gravity	-	-	-	-	1044.7
Beer gravity	-	-	-	-	1035.1
Spirit indication	-	-	-	-	9.6°

" Now the same beer gave by distillation, or the former method, a spirit indication of 9.9° . The new spirit indication by evaporation is, therefore, less by 0.3° than the old indication by distillation. The means were obtained of comparing the two indications given by the same fermented wort or beer in several hundred cases, by

adopting the practice of boiling the beer in a retort, instead of an open flask or basin, and collecting the alcohol at the same time. The evaporation uniformly indicated a quantity of spirits in the beer nearly the same as was obtained by distillation, but always sensibly less, as in the preceding instance. These experiments being made upon fermented liquids of known original gravity, the relation could always be observed between the new spirit indication and the degrees of specific gravity lost by the beer. Tables of the degrees of spirit indication, with their corresponding degrees of gravity lost, were thus constructed, exactly in the same manner as the tables which precede; and these new tables may be applied in the same way to ascertain the original gravity of any specimen of beer. Having found the degrees of spirit indication of the beer by evaporation, the corresponding degrees of gravity lost are taken from the table, and adding these degrees to the extract gravity of the beer, also observed, the original gravity is found. Thus the spirit indication (by the evaporation method) of the beer lately referred to, was 2.6° , which mark 48° of gravity lost in the new tables. Adding these to 1044.7, the extract gravity of the same beer, 1057.7 is obtained as the original gravity of the beer."

The results of the extensive series of experiments made, were, that the problem could be solved in the two extreme conditions in which they have only to deal with the pure sugars entirely converted into alcohol.

"The real difficulty is with the intermediate condition, which is also the most frequent one, where the solid matter of the beer is partly starch sugar and partly extractive; for no accurate chemical means are known of separating these substances, and so determining the quantity of each in the mixture.

"But a remedy presented itself. The fermentation of the beer was completed by the addition of yeast, and the constituents of the beer were thus reduced to alcohol and extractive only, from which the original gravity, as is seen, can be calculated.

"For this purpose a small but known measure of the beer, such as four fluid ounces, was carefully deprived of spirits by distillation, in a glass retort. To the fluid, when cooled, a charge of fresh yeast, amounting to 150 grains was added, and the mixture kept at 80° for a period of sixteen hours. Care was taken to connect the retort, from the commencement, with a tube condenser, so that the alcoholic vapour which exhaled from the wash during fermentation should not be lost. When the fermentation had entirely ceased, heat was applied to the retort to distil off the alcohol, which was collected in a cooled receiver. About three-fifths of the liquid were distilled over for this purpose; and the volume of the distillate was then made up with water in the original volume of the beer. The specific gravity of the last spirituous liquid was now taken by the weighing bottle. To obtain a correction for the small quantity of alcohol unavoidably introduced by the yeast, a parallel experiment was made with that substance. The same weight of yeast was mixed with water, and distilled in another similar retort. The volume of this second distillate was also made up by water to the beer volume; its specific gravity observed, and deducted from that of the preceding spirituous liquid. This alcohol was added to that obtained in the first distillation of the beer, and the weight of starch sugar corresponding to the whole amount of alcohol was calculated. This was the first result.

"For the solid matter of the beer: the spiritless liquid remaining in the retort was made up with water in the beer volume, and the specific gravity observed. A correction was also required here for the yeast, which is obtained by making up the water and yeast distilled in the second retort, to the original volume of the beer, and deducting the gravity of this fluid from the other. The quantity of starch sugar corresponding to this corrected gravity of the extractive matter was now furnished by the table. This was the second result.

"The two quantities of starch sugar thus obtained were added together. The specific gravity of the solution of the whole amount of starch sugar, as found in the table, represented the original gravity of the beer.

"This method must give an original gravity slightly higher than the truth, owing to the circumstance that the dextrin, albumen, and salts, which are found among the solid matters dissolved in beer, are treated as having the low gravity of extractive matter, and accordingly multiplied by about one-sixth, like that substance, in allowing for them ultimately as starch sugar. The error from this source, however, is inconsiderable. It is to be further observed, that the error from imperfect manipulation, of which there is most risk in the process, is leaving a little sugar in the extractive matter from incomplete fermentation. This accident also decreases the original gravity deduced. The process has given results which are remarkably uniform, and is valuable in the scientific investigation of the subject, although not of that ready and easy execution which is necessary for ordinary practice, and which recommends the former method."

TABLE V. — To be used in ascertaining Original Gravities by the Distillation Process.

FERRIC ACID. (FeO_3). This new compound having been prescribed as a source of supplying oxygen to persons confined in diving-bells and in mines, by M. Payenne, claims notice in a practical work. M. Fremy is the discoverer of this acid, which he obtains in the state of ferrate of potash, by projecting 10 parts of dry nitre to powder upon 5 parts of iron filings, ignited in a crucible; when a reddish mass, containing much ferrate of potash, is formed. The preparation succeeds best when a large crucible, capable of holding about a pint of water, is heated so strongly that the bottom and a couple of inches above it, appear faintly, but distinctly red, in which state the heat is still adequate to effect due deflagration without decomposition. An intimate mixture of about 200 grains of dried nitre with about one-half its weight of the finest iron filings, is to be thrown at once upon the side of the crucible. The mixture will soon swell and deflagrate. The crucible being taken from the fire, and the ignited mass being cooled, is to be taken out with an iron spoon, pounded, and immediately put into a bottle, and excluded from the air, from which it would speedily

attract moisture, and be decomposed. It is resolved by the action of water, especially with heat, into oxygen gas, peroxide, and nitrate of iron. This acid has not been obtained in a free state; it appears indeed to be scarcely capable of existing alone, decomposing, as soon as liberated, into oxygen and ferric oxide. — *Graham*.

Mr. J. D. Smith prepares the ferrate of potash by exposing to a full red heat a mixture of finely powdered peroxide of iron with four times its weight of dry nitre. It has an amethyst line, but so deep as to appear black, except at the edges. Oxygen is rapidly evolved by the action of the sulphuric or nitric acid upon its solution. He considers the atom of iron to exist in this compound associated with 3 atoms of oxygen, or double the proportion of that in the red oxide. Hence 52 grains of pure ferric acid should give off 12 grains of oxygen, equal to about 35 cubic inches; but how much of the ferrate of potash may be requisite to produce a like quantity of oxygen cannot be stated, from the uncertainty of the operation by which it is produced.

FERROCYANIDES. The compounds of the radical ferrocyanogen. The latter radical is bibasic, when, therefore, it combines with hydrogen to form ferrocyanic acid, it takes up two atoms. These two atoms of hydrogen can be replaced by metals as in ferrocyanide of potassium or prussiate of potash, as it is commonly called. See PRUSSIAN or POTASH. Ferrocyanogen consists of C^2N^4Fe , which may also be written Cy^4Fe , or, for brevity's sake, Cfy .

The modes of preparing the ferrocyanides differ, according as the resulting substance is soluble or insoluble in water. The soluble salts, such as those with alkalis, are prepared either by neutralising hydroferrocyanic acid with the proper metallic oxide, or by boiling prussian blue with the oxide, the metal of which it is intended to combine with the ferrocyanogen. Other methods may also be adopted in special cases. The processes for preparing the ferrocyanides of the alkali metals on the large scale will be described in the article PRUSSIAN or POTASH.

When the ferrocyanide is insoluble in water, it may be prepared by precipitating a salt of the metal with ferrocyanide of potassium. Thus, in the preparation of the reddish or purple ferrocyanide of copper,

The above equation written in full becomes:—

Ferrocyanide of potassium is much used as a test for various metals, in consequence of the characteristic colours of the precipitates formed with many of them. The principal ferrocyanides with their colours and modes of preparation will be found in the following list:—

Ferrocyanide of aluminium.—An instable compound formed by digesting hydrate of alumina with ferroproussic acid.

Ferrocyanides of antimony and arsenic.—Neither of these salts are known in a state of purity.

Ferrocyanide of barium.—This salt may be prepared by boiling prussian blue in slight excess with baryta water and evaporating to crystallisation.

Ferrocyanide of bismuth.—When a solution of ferrocyanide of potassium is added to a solution of a salt of bismuth, a yellow precipitate is obtained. It becomes of a greenish tint on keeping for some time.

Ferrocyanide of cadmium.—May be attained as a white precipitate on adding a solution of ferrocyanide of potassium to a soluble salt of cadmium.

Ferrocyanide of calcium.—May be prepared in the same manner as that of barium, but, owing to the sparing solubility of lime in water, we must substitute cream of lime for baryta water.

Ferrocyanide of cerium.—A white salt only slightly soluble in water. Its properties are very imperfectly known.

Ferrocyanide of chromium.—The protochloride of chromium gives a yellow precipitate with ferrocyanide of potassium.

Ferrocyanide of cobalt.—Salts of cobalt give a pale blue precipitate with ferrocyanide of potassium. It appears to decompose on keeping, as its colour becomes altered.

Ferrocyanide of copper.—When ferrocyanide of potassium is added to a solution of subchloride of copper, a white precipitate appears, which, on exposure, becomes converted into a purplish red substance, apparently identical with the ordinary ferrocyanide of copper which falls down on the admixture of salts of the protoxide of copper with solutions of ferrocyanide of potassium.

Ferrocyanide of glucinum.—May be obtained, according to Herzelsin, under the form of an amorphous varnish, by decomposing ferrocyanide of lead with a solution of sub-sulphate of glucina.

Ferrocyanide of hydrogen constitutes ferrocyanic acid.

Ferrocyanide of iron, or prussian blue.—This salt exists in several conditions, ac-

according to the mode of preparation. The ordinary salt is formed by adding a solution of ferrocyanide of potassium to a solution of a persalt of iron. The following equation explains the reaction that ensues with the sesquichloride:—

Ferrocyanide of lead is procured as a white precipitate by adding a solution of ferrocyanide of potassium to a salt of lead.

Ferrocyanide of magnesium is probably best prepared by neutralising ferroprussic acid with magnesia or its carbonate. It forms a pale yellow salt.

Ferrocyanide of manganese may be obtained as a white precipitate, on adding ferrocyanide of potassium to a solution of pure protochloride or protosulphate of manganese.

Ferrocyanide of mercury.—This compound cannot be obtained in a state of purity by precipitation. It has not been sufficiently examined.

Ferrocyanides of molybdenum.—Molybdenum salts give, with ferrocyanide of potassium, a dark brown precipitate soluble in excess of the precipitant. If a salt of molybdic oxide be treated in the same manner, a precipitate is obtained, having a similar appearance, but insoluble in excess. Molybdates in solution give precipitates lighter in colour than the last.

Ferrocyanide of nickel is obtained under the form of a pale apple green precipitate, on addition of prussiate of potash to a salt of nickel.

Ferrocyanide of silver.—Ferrocyanide of potassium gives a white precipitate with silver salts.

Ferrocyanide of sodium may be formed by the action of caustic soda on prussian blue.

Ferrocyanide of strontium can be procured precisely in the same manner as the corresponding barium salt substituting solution of caustic strontia (obtained from the nitrate by ignition) for baryta water.

Ferrocyanide of tantalum has probably never been obtained pure. Wollaston found that tantalic acid (dissolved in binodate of potash) gave a yellow precipitate with prussiate of potash.

Ferrocyanide of thorium.—A white precipitate is produced by the action of solution of prussiate of potash on salts of thorium.

Ferrocyanide of tin.—Pure salts of tin, whether of the per- or protoxide, give white precipitates with ferrocyanide of potassium.

Ferrocyanides of titanium.—Solutions of titanates give a golden brown precipitate when treated with solution of ferrocyanide of potassium.

Ferrocyanides of uranium.—The protochloride gives a pale, and the perchloride a dark reddish brown precipitate with ferrocyanide of potassium.

Ferrocyanide of vanadium.—Salts of vanadic oxide give pale yellow, and of vanadic acid, rich green precipitates with prussiate of potash.

Ferrocyanide of yttrium.—Chloride of yttrium gives a white precipitate with ferrocyanide of potassium.

Ferrocyanide of zinc cannot be prepared by precipitation. It may be obtained in the form of a white powder by the action of oxide or carbonate of zinc on ferroprussic acid.—C. G. W. For FERRO-CYANOGEN, see *Ure's Dictionary of Chemistry*.

FIBRES, or FIBROUS BODIES. From time to time numerous grasses, fibrous barks, and other substances of a similar character, have been introduced into commerce; a few of these only have been found available for manufacture. It is, however, deemed of interest to describe briefly some of these. Some of the more important vegetable fibres will be fully noticed under their respective heads. (See COIN, FLAX, HEMP, &c.)

China Grass.—This fibre is obtained from *Urtica aerea*, which grows abundantly in China, and in various parts of our Indian empire. The sample which have been imported are principally obtained from Canton and Hong Kong. In 1849, Messrs. Wright and Co. obtained a patent for the preparation of this fibre. Their process consisted essentially of boiling the stems in an alkaline solution, after they had been previously steeped for 24 hours in cold water, and for 24 hours in water at 90° Fahr. The fibre is then thoroughly washed with pure water, and finally subjected to the action of a current of high pressure steam till nearly dry.

Calloose Hemp or Rhea.—This fibre is usually confounded with China grass; but, there is little doubt they are obtained from two different kinds of urtica. The China grass from the *Urtica aerea* of Willdenow; the Calloose Hemp, *Kulmoi*, or *Rami*, of Sumatra; and the *Rhea* from the *Urtica tenuissima* of Roxburgh. The plant producing the Calloose hemp, was introduced from Bencoolen to Calcutta in 1803, where, under the care of Dr. Roxburgh, it was for many years cultivated in the Botanic Gardens. In 1811, a quantity of the Calloose hemp was imported into England, and properly tested; its practical value was thought so highly of, that the Society of Arts awarded a silver medal to Capt. James Cotton, of the East India Company, who in-

produced it. "The chief obstacle which interfered, however, with its use, was the difficulty which was found to exist in the preparation of the fibre from the stems of the plants; none of the processes usually adopted with flax or hemp were found to be at all suitable to them; and the rude, wasteful, and imperfect means employed by the natives in preparing the fibre for the manufacture of twine, thread, and fishing nets, by the mere process of scraping, were wholly inapplicable on a large scale, and gave besides only a very inferior result. When macerated or retted in water, it was found that the fibre itself was more easily destroyed than the glutinous matter of the stem. During the last forty years, various attempts have been made to devise a good and cheap process for preparing this fibre, but hitherto without much success; and consequently, till quite recently, the cost of the fibre was such as to preclude its being brought into the market as a substitute for flax. But recent investigations have shown that the *Urtica tenacissima* and the *heterophylla* may be obtained in almost unlimited quantities in various parts of India; and a process which has been lately patented appears, to a very great extent, to have removed the practical difficulties which previously stood in the way of its employment by manufacturers; so that in a few years it is probable that the Calicoe hemp will constitute an important addition to the fibrous materials employed in the arts." *Juror's Report, Great Exhibition, 1851.*
